About the Editor

Frank J. Fabozzi is Professor of Finance at EDHEC Business School and a member of the EDHEC Risk Institute. Prior to joining EDHEC in August 2011, he held various professorial positions in finance at Yale University's School of Management from 1994 to 2011 and from 1986 to 1992 was a visiting professor of finance and accounting at MIT's Sloan School of Management. From 2008 to 2011, he was an affiliated professor in the Institute of Statistics, Econometrics, and Mathematical Finance at the University of Karlsruhe in Germany. Prior to 1986 he held professorial positions at Lafayette College, Fordham University, Queens College (CUNY), and Hofstra University. From 2003 to 2011, he served on Princeton University's Advisory Council for the Department of Operations Research and Financial Engineering and since then has been a visiting fellow in that department.

Professor Fabozzi is the editor of the *Journal of Portfolio Management*, as well as on the editorial board of the *Journal of Fixed Income*, *Journal of Asset Management*, *Quantitative Finance*, *Review of Futures Markets*, *Journal of Mathematical Finance*, *Journal of Structured Finance*, *Annals of Financial Economics*, and *Theoretical Economic Letters*.

He has authored and edited a number of books in asset management and quantitative finance. His coauthored books in quantitative finance include *A Probability Metrics Approach to Financial Risk Measures* (2011), *Financial Modeling with Lévy Processes and Volatility Clustering* (2011), *Quantitative Equity Investing: Techniques and Strategies* (2010), *Probability and Statistics for Finance* (2010), *Simulation and Optimization Modeling in Finance* (2010), *Bayesian Methods in Finance* (2008), *Advanced Stochastic Models, Risk Assessment, and Portfolio Optimization: The Ideal Risk* (2008), *Financial Econometrics: From Basics to Advanced Modeling Techniques* (2007), *Robust Portfolio Optimization and Management* (2007), and *Mathematics of Financial Modeling and Investment Management* (2004). His books in applied mathematics include *The Methods of Distances in the Theory of Probability and Statistics* (2013) and *Robust and Non-Robust Models in Statistics* (2009). He coauthored three monographs for the Research Foundation of the CFA Institute: *The Impact of the Financial Crisis on the Asset Management Industry* (2010), *Challenges in Quantitative Equity Management* (2008), and *Trends in Quantitative Finance* (2006).

Professor Fabozzi's research papers have appeared in numerous journals, including *Journal of Finance*, *Journal of Finance and Quantitative Analysis*, *Econometric Theory*, *Operations Research*, *Journal of Banking and Finance*, *Journal of Economic Dynamics and Control*, *Studies in Nonlinear Dynamics and Econometrics*, *European Journal of Operational Research*, *Annals of Operations Research*, *Quantitative Finance*, *European Financial Management*, and *The Econometric Journal*. His 2010 article published in *European Financial Management* with Professors Robert Shiller, and Radu Tunaru, "Property Derivatives for Managing European Real-Estate Risk," received the Best Paper Award and his paper with the same coauthors entitled "A Pricing Framework for Real Estate Derivatives" was awarded

Best Research Paper at the 10th Research Conference Campus for Finance held annually at WHU Otto Beisheim School of Management, Vallendar, Germany. An article coauthored with Dr. Sergio Focardi, "An Autoregressive Conditional Duration Model of Credit Risk Contagion," published in 2005 in *Journal of Risk Finance* was the winner of the 2006 Outstanding Paper by Emerald Literati Network.

He has received several awards and honors for his body of work. In 1994 he was awarded an Honorary Doctorate of Humane Letters from Nova Southeastern University. In 2002 he was inducted into the Fixed Income Analysts Society's Hall of Fame, established by the society "to recognize the lifetime achievements of outstanding practitioners in the advancement of the analysis of fixed-income securities and portfolios." In 2007 he was the recipient of the C. Stewart Sheppard Award given by the CFA Institute "in recognition of outstanding contribution to continuing education in the CFA profession." He was the cover story in the July 1999 issue of *Bloomberg Magazine* entitled "The Boswell of Bonds."

Professor Fabozzi was the co-founder of Information Management Network (now a subsidiary of Euromoney), a conference company specializing in financial topics. He is a trustee for the BlackRock family of closed-end funds where he is the chair of the performance committee and a member of the audit committee. He was a director of Guardian Mutual Funds and Guardian Annuity Funds.

He earned both an M.A. and B.A. in economics and statistics in June 1970 from the City College of New York and elected to Phi Beta Kappa in 1969. He earned a Ph.D. in Economics in September 1972 from the City University of New York. Professor Fabozzi holds two professional designations: Chartered Financial Analyst (1977) and Certified Public Accountant (1982).

Preface

It is often said that investment management is an art, not a science. However, since the early 1990s the market has witnessed a progressive shift toward a more industrial view of the investment management process. There are several reasons for this change. First, with globalization the universe of investable assets has grown many times over. Asset managers might have to choose from among several thousand possible investments from around the globe. Second, institutional investors, often together with their consultants, have encouraged asset management firms to adopt an increasingly structured process with documented steps and measurable results. Pressure from regulators and the media is another factor. Finally, the sheer size of the markets makes it imperative to adopt safe and repeatable methodologies.

In its modern sense, financial modeling is the design (or engineering) of financial instruments and portfolios of financial instruments that result in predetermined cash flows contingent upon different events. Broadly speaking, financial models are employed to manage investment portfolios and risk. The objective is the transfer of risk from one entity to another via appropriate financial arrangements. Though the aggregate risk is a quantity that cannot be altered, risk can be transferred if there is a willing counterparty.

Financial modeling came to the forefront of finance in the 1980s, with the broad diffusion

of derivative instruments. However, the concept and practice of financial modeling are quite old. The notion of the diversification of risk (central to modern risk management) and the quantification of insurance risk (a requisite for pricing insurance policies) were already understood, at least in practical terms, in the 14th century. The rich epistolary of Francesco Datini, a 14th-century merchant, banker, and insurer from Prato (Tuscany, Italy), contains detailed instructions to his agents on how to diversify risk and insure cargo.

What is specific to modern financial modeling is the quantitative management of risk. Both the pricing of contracts and the optimization of investments require some basic capabilities of statistical modeling of financial contingencies. It is the size, diversity, and efficiency of modern competitive markets that makes the use of financial modeling imperative.

This three-volume encyclopedia offers not only coverage of the fundamentals and advances in financial modeling but provides the mathematical and statistical techniques needed to develop and test financial models, as well as the practical issues associated with implementation. The encyclopedia offers the following unique features:

- The entries for the encyclopedia were written by experts from around the world. This diverse collection of expertise has created the most definitive coverage of established and

cutting-edge financial models, applications, and tools in this ever-evolving field.

- The series emphasizes both technical and managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding of the topics and the necessary background to deal with issues related to financial modeling.
- Each entry follows a format that includes the author, entry abstract, introduction, body, listing of key points, notes, and references. This enables readers to pick and choose among various sections of an entry, and creates consistency throughout the entire encyclopedia.
- The numerous illustrations and tables throughout the work highlight complex topics and assist further understanding.
- Each volume includes a complete table of contents and index for easy access to various parts of the encyclopedia.

TOPIC CATEGORIES

As is the practice in the creation of an encyclopedia, the topic categories are presented alphabetically. The topic categories and a brief description of each topic follow.

VOLUME I

Asset Allocation

A major activity in the investment management process is establishing policy guidelines to satisfy the investment objectives. Setting policy begins with the asset allocation decision. That is, a decision must be made as to how the funds to be invested should be distributed among the major asset classes (e.g., equities, fixed income, and alternative asset classes). The term “asset allocation” includes (1) policy asset allocation, (2) dynamic asset allocation, and (3) tactical asset allocation. Policy asset allocation decisions can loosely be characterized as long-term asset allocation decisions, in which the investor seeks to assess an appropriate long-term “normal” asset mix that represents an ideal blend of controlled risk and enhanced return. In dynamic asset allocation the asset mix (i.e., the

allocation among the asset classes) is mechanically shifted in response to changing market conditions. Once the policy asset allocation has been established, the investor can turn his or her attention to the possibility of active departures from the normal asset mix established by policy. If a decision to deviate from this mix is based upon rigorous objective measures of value, it is often called tactical asset allocation. The fundamental model used in establishing the policy asset allocation is the mean-variance portfolio model formulated by Harry Markowitz in 1952, popularly referred to as the theory of portfolio selection and modern portfolio theory.

Asset Pricing Models

Asset pricing models seek to formalize the relationship that should exist between asset returns and risk if investors behave in a hypothesized manner. At its most basic level, asset pricing is mainly about transforming asset payoffs into prices. The two most well-known asset pricing models are the arbitrage pricing theory and the capital asset pricing model. The fundamental theorem of asset pricing asserts the equivalence of three key issues in finance: (1) absence of arbitrage; (2) existence of a positive linear pricing rule; and (3) existence of an investor who prefers more to less and who has maximized his or her utility. There are two types of arbitrage opportunities. The first is paying nothing today and obtaining something in the future, and the second is obtaining something today and with no future obligations. Although the principle of absence of arbitrage is fundamental for understanding asset valuation in a competitive market, there are well-known limits to arbitrage resulting from restrictions imposed on rational traders, and, as a result, pricing inefficiencies may exist for a period of time.

Bayesian Analysis and Financial Modeling Applications

Financial models describe in mathematical terms the relationships between financial random variables through time and/or across assets. The fundamental assumption is that the

model relationship is valid independent of the time period or the asset class under consideration. Financial data contain both meaningful information and random noise. An adequate financial model not only extracts optimally the relevant information from the historical data but also performs well when tested with new data. The uncertainty brought about by the presence of data noise makes imperative the use of statistical analysis as part of the process of financial model building, model evaluation, and model testing. Statistical analysis is employed from the vantage point of either of the two main statistical philosophical traditions—frequentist and Bayesian. An important difference between the two lies with the interpretation of the concept of probability. As the name suggests, advocates of the frequentist approach interpret the probability of an event as the limit of its long-run relative frequency (i.e., the frequency with which it occurs as the amount of data increases without bound). Since the time financial models became a mainstream tool to aid in understanding financial markets and formulating investment strategies, the framework applied in finance has been the frequentist approach. However, strict adherence to this interpretation is not always possible in practice. When studying rare events, for instance, large samples of data may not be available, and in such cases proponents of frequentist statistics resort to theoretical results. The Bayesian view of the world is based on the subjectivist interpretation of probability: Probability is subjective, a degree of belief that is updated as information or data are acquired. Only in the last two decades has Bayesian statistics started to gain greater acceptance in financial modeling, despite its introduction about 250 years ago. It has been the advancements of computing power and the development of new computational methods that have fostered the growing use of Bayesian statistics in financial modeling.

Bond Valuation

The value of any financial asset is the present value of its expected future cash flows. To value

a bond (also referred to as a fixed-income security), one must be able to estimate the bond's remaining cash flows and identify the appropriate discount rate(s) at which to discount the cash flows. The traditional approach to bond valuation is to discount every cash flow with the same discount rate. Simply put, the relevant term structure of interest rate used in valuation is assumed to be flat. This approach, however, permits opportunities for arbitrage. Alternatively, the arbitrage-free valuation approach starts with the premise that a bond should be viewed as a portfolio or package of zero-coupon bonds. Moreover, each of the bond's cash flows is valued using a unique discount rate that depends on the term structure of interest rates and when in time the cash flow is. The relevant set of discount rates (that is, spot rates) is derived from an appropriate term structure of interest rates and when used to value risky bonds augmented with a suitable risk spread or premium. Rather than modeling to calculate the fair value of its price, the market price can be taken as given so as to compute a yield measure or a spread measure. Popular yield measures are the yield to maturity, yield to call, yield to put, and cash flow yield. Nominal spread, static (or zero-volatility) spread, and option-adjusted spread are popular relative value measures quoted in the bond market. Complications in bond valuation arise when a bond has one or more embedded options such as call, put, or conversion features. For bonds with embedded options, the financial modeling draws from options theory, more specifically, the use of the lattice model to value a bond with embedded options.

Credit Risk Modeling

Credit risk is a broad term used to refer to three types of risk: default risk, credit spread risk, and downgrade risk. Default risk is the risk that the counterparty to a transaction will fail to satisfy the terms of the obligation with respect to the timely payment of interest and repayment of the amount borrowed. The counterparty could be the issuer of a debt obligation or an entity on

the other side of a private transaction such as a derivative trade or a collateralized loan agreement (i.e., a repurchase agreement or a securities lending agreement). The default risk of a counterparty is often initially gauged by the credit rating assigned by one of the three rating companies—Standard & Poor’s, Moody’s Investors Service, and Fitch Ratings. Although default risk is the one that most market participants think of when reference is made to credit risk, even in the absence of default, investors are concerned about the decline in the market value of their portfolio bond holdings due to a change in credit spread or the price performance of their holdings relative to a bond index. This risk is due to an adverse change in credit spreads, referred to as credit spread risk, or when it is attributed solely to the downgrade of the credit rating of an entity, it is called downgrade risk. Financial modeling of credit risk is used (1) to measure, monitor, and control a portfolio’s credit risk, and (2) to price credit risky debt instruments. There are two general categories of credit risk models: structural models and reduced-form models. There is considerable debate as to which type of model is the best to employ.

Derivatives Valuation

A derivative instrument is a contract whose value depends on some underlying asset. The term “derivative” is used to describe this product because its value is derived from the value of the underlying asset. The underlying asset, simply referred to as the “underlying,” can be either a commodity, a financial instrument, or some reference entity such as an interest rate or stock index, leading to the classification of commodity derivatives and financial derivatives. Although there are close conceptual relations between derivative instruments and cash market instruments such as debt and equity, the two classes of instruments are used differently: Debt and equity are used primarily for raising funds from investors, while derivatives are primarily

used for dividing up and trading risks. Moreover, debt and equity are direct claims against a firm’s assets, while derivative instruments are usually claims on a third party. A derivative’s value depends on the value of the underlying, but the derivative instrument itself represents a claim on the “counterparty” to the trade. Derivatives instruments are classified in terms of their payoff characteristics: linear and nonlinear payoffs. The former, also referred to as symmetric payoff derivatives, includes forward, futures, and swap contracts while the latter include options. Basically, a linear payoff derivative is a risk-sharing arrangement between the counterparties since both are sharing the risk regarding the price of the underlying. In contrast, nonlinear payoff derivative instruments (also referred to as asymmetric payoff derivatives) are insurance arrangements because one party to the trade is willing to insure the counterparty of a minimum or maximum (depending on the contract) price. The amount received by the insuring party is referred to as the contract price or premium. Derivative instruments are used for controlling risk exposure with respect to the underlying. Hedging is a special case of risk control where a party seeks to eliminate the risk exposure. Derivative valuation or pricing is developed based on no-arbitrage price relations, relying on the assumption that two perfect substitutes must have the same price.

Difference Equations and Differential Equations

The tools of linear difference equations and differential equations have found many applications in finance. A difference equation is an equation that involves differences between successive values of a function of a discrete variable. A function of such a variable is one that provides a rule for assigning values in sequences to it. The theory of linear difference equations covers three areas: solving difference equations, describing the behavior

of difference equations, and identifying the equilibrium (or critical value) and stability of difference equations. Linear difference equations are important in the context of dynamic econometric models. Stochastic models in finance are expressed as linear difference equations with random disturbances added. Understanding the behavior of solutions of linear difference equations helps develop intuition for the behavior of these models. In nontechnical terms, differential equations are equations that express a relationship between a function and one or more derivatives (or differentials) of that function. The relationship between difference equations and differential equations is that the latter are invaluable for modeling situations in finance where there is a continually changing value. The problem is that not all changes in value occur continuously. If the change in value occurs incrementally rather than continuously, then differential equations have their limitations. Instead, a financial modeler can use difference equations, which are recursively defined sequences. It would be difficult to overemphasize the importance of differential equations in financial modeling where they are used to express laws that govern the evolution of price probability distributions, the solution of economic variational problems (such as intertemporal optimization), and conditions for continuous hedging (such as in the Black-Scholes option pricing model). The two broad types of differential equations are ordinary differential equations and partial differential equations. The former are equations or systems of equations involving only one independent variable. Another way of saying this is that ordinary differential equations involve only total derivatives. Partial differential equations are differential equations or systems of equations involving partial derivatives. When one or more of the variables is a stochastic process, we have the case of stochastic differential equations and the solution is also a stochastic process. An assumption must be made about what is driving noise in a stochastic differential

equation. In most applications, it is assumed that the noise term follows a Gaussian random variable, although other types of random variables can be assumed.

Equity Models and Valuation

Traditional fundamental equity analysis involves the analysis of a company's operations for the purpose of assessing its economic prospects. The analysis begins with the financial statements of the company in order to investigate the earnings, cash flow, profitability, and debt burden. The fundamental analyst will look at the major product lines, the economic outlook for the products (including existing and potential competitors), and the industries in which the company operates. The result of this analysis will be the growth prospects of earnings. Based on the growth prospects of earnings, a fundamental analyst attempts to determine the fair value of the stock using one or more equity valuation models. The two most commonly used approaches for valuing a firm's equity are based on discounted cash flow and relative valuation models. The principal idea underlying discounted cash flow models is that what an investor pays for a share of stock should reflect what is expected to be received from it—return on the investor's investment. What an investor receives are cash dividends in the future. Therefore, the value of a share of stock should be equal to the present value of all the future cash flows an investor expects to receive from that share. To value stock, therefore, an investor must project future cash flows, which, in turn, means projecting future dividends. Popular discounted cash flow models include the basic dividend discount model, which assumes a constant dividend growth, and the multiple-phase models, which include the two-stage dividend growth model and the stochastic dividend discount models. Relative valuation methods use multiples or ratios—such as price/earnings, price/book, or price/free cash flow—to determine whether a stock is trading at higher or lower multiples than its peers.

There are two critical assumptions in using relative valuation: (1) the universe of firms selected to be included in the peer group are in fact comparable, and (2) the average multiple across the universe of firms can be treated as a reasonable approximation of “fair value” for those firms. This second assumption may be problematic during periods of market panic or euphoria. Managers of quantitative equity firms employ techniques that allow them to identify attractive stock candidates, focusing not on a single stock as is done with traditional fundamental analysis but rather on stock characteristics in order to explain why one stock outperforms another stock. They do so by statistically identifying a group of characteristics to create a quantitative selection model. In contrast to the traditional fundamental stock selection, quantitative equity managers create a repeatable process that utilizes the stock selection model to identify attractive stocks. Equity portfolio managers have used various statistical models for forecasting returns and risk. These models, referred to as predictive return models, make conditional forecasts of expected returns using the current information set. Predictive return models include regressive models, linear autoregressive models, dynamic factor models, and hidden-variable models.

Factor Models and Portfolio Construction

Quantitative asset managers typically employ multifactor risk models for the purpose of constructing and rebalancing portfolios and analyzing portfolio performance. A multifactor risk model, or simply factor model, attempts to estimate and characterize the risk of a portfolio, either relative to a benchmark such as a market index or in absolute value. The model allows the decomposition of risk factors into a systematic and an idiosyncratic component. The portfolio’s risk exposure to broad risk factors is captured by the systematic risk. For equity portfolios these are typically fundamental factors (e.g., market capitalization and value

vs. growth), technical (e.g., momentum), and industry/sector/country. For fixed-income portfolios, systematic risk captures a portfolio’s exposure to broad risk factors such as the term structure of interest rates, credit spreads, optionality (call and prepayment), credit, and sectors. The portfolio’s systematic risk depends not only on its exposure to these risk factors but also the volatility of the risk factors and how they correlate with each other. In contrast to systematic risk, idiosyncratic risk captures the uncertainty associated with news affecting the holdings of individual issuers in the portfolio. In equity portfolios, idiosyncratic risk can be easily diversified by reducing the importance of individual issuers in the portfolio. Because of the larger number of issuers in bond indexes, however, this is a difficult task. There are different types of factor models depending on the factors. Factors can be exogenous variables or abstract variables formed by portfolios. Exogenous factors (or known factors) can be identified from traditional fundamental analysis or from economic theory that suggests macroeconomic factors. Abstract factors, also called unidentified or latent factors, can be determined with the statistical tool of factor analysis or principal component analysis. The simplest type of factor models is where the factors are assumed to be known or observable, so that time-series data are those factors that can be used to estimate the model. The four most commonly used approaches for the evaluation of return premiums and risk characteristics to factors are portfolio sorts, factor models, factor portfolios, and information coefficients. Despite its use by quantitative asset managers, the basic building blocks of factor models used by model builders and by traditional fundamental analysts are the same: They both seek to identify the drivers of returns for the asset class being analyzed.

Financial Econometrics

Econometrics is the branch of economics that draws heavily on statistics for testing and

analyzing economic relationships. The economic equivalent of the laws of physics, econometrics represents the quantitative, mathematical laws of economics. Financial econometrics is the econometrics of financial markets. It is a quest for models that describe financial time series such as prices, returns, interest rates, financial ratios, defaults, and so on. Although there are similarities between financial econometric models and models of the physical sciences, there are two important differences. First, the physical sciences aim at finding immutable laws of nature; econometric models model the economy or financial markets—artifacts subject to change. Because the economy and financial markets are artifacts subject to change, econometric models are not unique representations valid throughout time; they must adapt to the changing environment. Second, while basic physical laws are expressed as differential equations, financial econometrics uses both continuous-time and discrete-time models.

Financial Modeling Principles

The origins of financial modeling can be traced back to the development of mathematical equilibrium at the end of the nineteenth century, followed in the beginning of the twentieth century with the introduction of sophisticated mathematical tools for dealing with the uncertainty of prices and returns. In the 1950s and 1960s, financial modelers had tools for dealing with probabilistic models for describing markets, the principles of contingent claims analysis, an optimization framework for portfolio selection based on mean and variance of asset returns, and an equilibrium model for pricing capital assets. The 1970s ushered in models for pricing contingent claims and a new model for pricing capital assets based on arbitrage pricing. Consequently, by the end of the 1970s, the frameworks for financial modeling were well known. It was the advancement of computing power and refinements of the theories to take into account real-world market imperfections and

conventions starting in the 1980s that facilitated implementation and broader acceptance of mathematical modeling of financial decisions. The diffusion of low-cost high-performance computers has allowed the broad use of numerical methods, the landscape of financial modeling. The importance of finding closed-form solutions and the consequent search for simple models has been dramatically reduced. Computationally intensive methods such as Monte Carlo simulations and the numerical solution of differential equations are now widely used. As a consequence, it has become feasible to represent prices and returns with relatively complex models. Nonnormal probability distributions have become commonplace in many sectors of financial modeling. It is fair to say that the key limitation of financial modeling is now the size of available data samples or training sets, not the computations; it is the data that limit the complexity of estimates. Mathematical modeling has also undergone major changes. Techniques such as equivalent martingale methods are being used in derivative pricing, and cointegration, the theory of fat-tailed processes, and state-space modeling (including ARCH/GARCH and stochastic volatility models) are being used in financial modeling.

Financial Statement Analysis

Much of the financial data that are used in constructing financial models for forecasting and valuation purposes draw from the financial statements that companies are required to provide to investors. The four basic financial statements are the balance sheet, the income statement, the statement of cash flows, and the statement of shareholders' equity. It is important to understand these data so that the information conveyed by them is interpreted properly in financial modeling. The financial statements are created using several assumptions that affect how to use and interpret the financial data. The analysis of financial statements involves the selection, evaluation, and

interpretation of financial data and other pertinent information to assist in evaluating the operating performance and financial condition of a company. The operating performance of a company is a measure of how well a company has used its resources—its assets, both tangible and intangible—to produce a return on its investment. The financial condition of a company is a measure of its ability to satisfy its obligations, such as the payment of interest on its debt in a timely manner. There are many tools available in the analysis of financial information. These tools include financial ratio analysis and cash flow analysis. Cash flows are essential ingredients in valuation. Therefore, understanding past and current cash flows may help in forecasting future cash flows and, hence, determine the value of the company. Moreover, understanding cash flow allows the assessment of the ability of a firm to maintain current dividends and its current capital expenditure policy without relying on external financing. Financial modelers must understand how to use these financial ratios and cash flow information in the most effective manner in building models.

Finite Mathematics and Basic Functions for Financial Modeling

The collection of mathematical tools that does not include calculus is often referred to as “finite mathematics.” This includes matrix algebra, probability theory, and statistical analysis. Ordinary algebra deals with operations such as addition and multiplication performed on individual numbers. In financial modeling, it is useful to consider operations performed on ordered arrays of numbers. Ordered arrays of numbers are called vectors and matrices while individual numbers are called scalars. Probability theory is the mathematical approach to formalize the uncertainty of events. Even though a decision maker may not know which one of the set of possible events may finally occur, with probability theory a decision maker has the means of providing each event with

a certain probability. Furthermore, it provides the decision maker with the axioms to compute the probability of a composed event in a unique way. The rather formal environment of probability theory translates in a reasonable manner to the problems related to risk and uncertainty in finance such as, for example, the future price of a financial asset. Today, investors may be aware of the price of a certain asset, but they cannot say for sure what value it might have tomorrow. To make a prudent decision, investors need to assess the possible scenarios for tomorrow’s price and assign to each scenario a probability of occurrence. Only then can investors reasonably determine whether the financial asset satisfies an investment objective included within a portfolio. Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). There are important mathematical functions with which the financial modeler should be acquainted. These include the continuous function, the indicator function, the derivative of a function, the monotonic function, and the integral, as well as special functions such as the characteristic function of random variables and the factorial, the gamma, beta, and Bessel functions.

Liquidity and Trading Costs

In broad terms, liquidity refers to the ability to execute a trade or liquidate a position with little or no cost or inconvenience. Liquidity depends on the market where a financial instrument is traded, the type of position traded, and sometimes the size and trading strategy of an individual trade. Liquidity risks are those associated with the prospect of imperfect market liquidity and can relate to risk of loss or

risk to cash flows. There are two main aspects to liquidity risk measurement: the measurement of liquidity-adjusted measures of market risk and the measurement of liquidity risks per se. Market practitioners often assume that markets are liquid—that is, that they can liquidate or unwind positions at going market prices—usually taken to be the mean of bid and ask prices—without too much difficulty or cost. This assumption is very convenient and provides a justification for the practice of marking positions to market prices. However, it is often empirically questionable, and the failure to allow for liquidity can undermine the measurement of market risk. Because liquidity risk is a major risk factor in its own right, portfolio managers and traders will need to measure this risk in order to formulate effective portfolio and trading strategies. A considerable amount of work has been done in the equity market in estimating liquidity risk. Because transaction costs are incurred when buying or selling stocks, poorly executed trades can adversely impact portfolio returns and therefore relative performance. Transaction costs are classified as explicit costs such as brokerage and taxes, and implicit costs, which include market impact cost, price movement risk, and opportunity cost. Broadly speaking, market impact cost is the price that a trader has to pay for obtaining liquidity in the market and is a key component of trading costs that must be modeled so that effective trading programs for executing trades can be developed. Typical forecasting models for market impact costs are based on a statistical factor approach where the independent variables are trade-based factors or asset-based factors.

Model Risk and Selection

Model risk is the risk of error in pricing or risk-forecasting models. In practice, model risk arises because (1) any model involves simpli-

fication and calibration, and both of these require subjective judgments that are prone to error, and/or (2) a model is used inappropriately. Although model risk cannot be avoided, there are many ways in which financial modelers can manage this risk. These include (1) recognizing model risk, (2) identifying, evaluating, and checking the model's key assumption, (3) selecting the simplest reasonable model, (4) resisting the temptation to ignore small discrepancies in results, (5) testing the model against known problems, (6) plotting results and employing nonparametric statistics, (7) back-testing and stress-testing the model, (8) estimating model risk quantitatively, and (9) reevaluating models periodically. In financial modeling, model selection requires a blend of theory, creativity, and machine learning. The machine-learning approach starts with a set of empirical data that the financial modeler wants to explain. Data are explained by a family of models that include an unbounded number of parameters and are able to fit data with arbitrary precision. There is a trade-off between model complexity and the size of the data sample. To implement this trade-off, ensuring that models have forecasting power, the fitting of sample data is constrained to avoid fitting noise. Constraints are embodied in criteria such as the Akaike information criterion or the Bayesian information criterion. Economic and financial data are generally scarce given the complexity of their patterns. This scarcity introduces uncertainty as regards statistical estimates obtained by the financial modeler. It means that the data might be compatible with many different models with the same level of statistical confidence. Methods of probabilistic decision theory can be used to deal with model risk due to uncertainty regarding the model's parameters. Probabilistic decision making starts from the Bayesian inference process and involves computer simulations in all realistic situations. Since a risk model is typically a combination of a probability distribution model and a risk measure, a critical assumption is the probability distribution assumed for

the random variable of interest. Too often, the Gaussian distribution is the model of choice. Empirical evidence supports the use of probability distributions that exhibit fat tails such as the Student's t distribution and its asymmetric version and the Pareto stable class of distributions and their tempered extensions. Extreme value theory offers another approach for risk modeling.

Mortgage-Backed Securities Analysis and Valuation

Mortgage-backed securities are fixed-income securities backed by a pool of mortgage loans. Residential mortgage-backed securities (RMBS) are backed by a pool of residential mortgage loans (one-to-four family dwellings). The RMBS market includes agency RMBS and nonagency RMBS. The former are securities issued by the Government National Mortgage Association (Ginnie Mae), Fannie Mae, and Freddie Mac. Agency RMBS include passthrough securities, collateralized mortgage obligations, and stripped mortgage-backed securities (interest-only and principal-only securities). The valuation of RMBS is complicated due to prepayment risk, a form of call risk. In contrast, nonagency RMBS are issued by private entities, have no implicit or explicit government guarantee, and therefore require one or more forms of credit enhancement in order to be assigned a credit rating. The analysis of nonagency RMBS must take into account both prepayment risk and credit risk. The most commonly used method for valuing RMBS is the Monte Carlo method, although other methods have garnered favor, in particular the decomposition method. The analysis of RMBS requires an understanding of the factors that impact prepayments.

Operational Risk

Operational risk has been regarded as a mere part of a financial institution's "other" risks. However, failures of major financial entities

have made regulators and investors aware of the importance of this risk. In general terms, operational risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. This risk encompasses legal risks, which includes, but is not limited to, exposure to fines, penalties, or punitive damages resulting from supervisory actions, as well as private settlements. Operational risk can be classified according to several principles: nature of the loss (internally inflicted or externally inflicted), direct losses or indirect losses, degree of expectancy (expected or unexpected), risk type, event type or loss type, and by the magnitude (or severity) of loss and the frequency of loss. Operational risk can be the cause of reputational risk, a risk that can occur when the market reaction to an operational loss event results in reduction in the market value of a financial institution that is greater than the amount of the initial loss. The two principal approaches in modeling operational loss distributions are the nonparametric approach and the parametric approach. It is important to employ a model that captures tail events, and for this reason in operational risk modeling, distributions that are characterized as light-tailed distributions should be used with caution. The models that have been proposed for assessing operational risk can be broadly classified into top-down models and bottom-up models. Top-down models quantify operational risk without attempting to identify the events or causes of losses. Bottom-up models quantify operational risk on a micro level, being based on identified internal events. The obstacle hindering the implementation of these models is the scarcity of available historical operational loss data.

Optimization Tools

Optimization is an area in applied mathematics that, most generally, deals with efficient algorithms for finding an optimal solution among a set of solutions that satisfy given constraints. Mathematical programming, a management

science tool that uses mathematical optimization models to assist in decision making, includes linear programming, integer programming, mixed-integer programming, nonlinear programming, stochastic programming, and goal programming. Unlike other mathematical tools that are available to decision makers such as statistical models (which tell the decision maker what occurred in the past), forecasting models (which tell the decision maker what might happen in the future), and simulation models (which tell the decision maker what will happen under different conditions), mathematical programming models allow the decision maker to identify the “best” solution. Markowitz’s mean-variance model for portfolio selection is an example of an application of one type of mathematical programming (quadratic programming). Traditional optimization modeling assumes that the inputs to the algorithms are certain, but there are also branches of optimization such as robust optimization that study the optimal decision under uncertainty about the parameters of the problem. Stochastic programming deals with both the uncertainty about the parameters and a multiperiod decision-making framework.

Probability Distributions

In financial models where the outcome of interest is a random variable, an assumption must be made about the random variable’s probability distribution. There are two types of probability distributions: discrete and continuous. Discrete probability distributions are needed whenever the random variable is to describe a quantity that can assume values from a countable set, either finite or infinite. A discrete probability distribution (or law) is quite intuitive in that it assigns certain values, positive probabilities, adding up to one, while any other value automatically has zero probability. Continuous probability distributions are needed when the random variable of interest can assume any value inside of one or more

intervals of real numbers such as, for example, any number greater than zero. Asset returns, for example, whether measured monthly, weekly, daily, or at an even higher frequency are commonly modeled as continuous random variables. In contrast to discrete probability distributions that assign positive probability to certain discrete values, continuous probability distributions assign zero probability to any single real number. Instead, only entire intervals of real numbers can have positive probability such as, for example, the event that some asset return is not negative. For each continuous probability distribution, this necessitates the so-called probability density, a function that determines how the entire probability mass of one is distributed. The density often serves as the proxy for the respective probability distribution. To model the behavior of certain financial assets in a stochastic environment, a financial modeler can usually resort to a variety of theoretical distributions. Most commonly, probability distributions are selected that are analytically well known. For example, the normal distribution (a continuous distribution)—also called the Gaussian distribution—is often the distribution of choice when asset returns are modeled. Or the exponential distribution is applied to characterize the randomness of the time between two successive defaults of firms in a bond portfolio. Many other distributions are related to them or built on them in a well-known manner. These distributions often display pleasant features such as stability under summation—meaning that the return of a portfolio of assets whose returns follow a certain distribution again follows the same distribution. However, one has to be careful using these distributions since their advantage of mathematical tractability is often outweighed by the fact that the stochastic behavior of the true asset returns is not well captured by these distributions. For example, although the normal distribution generally renders modeling easy because all moments of the distribution exist, it fails to reflect stylized facts commonly encountered in

asset returns—namely, the possibility of very extreme movements and skewness. To remedy this shortcoming, probability distributions accounting for such extreme price changes have become increasingly popular. Some of these distributions concentrate exclusively on the extreme values while others permit any real number, but in a way capable of reflecting market behavior. Consequently, a financial modeler has available a great selection of probability distributions to realistically reproduce asset price changes. Their common shortcoming is generally that they are mathematically difficult to handle.

Risk Measures

The standard assumption in financial models is that the distribution for the return on financial assets follows a normal (or Gaussian) distribution and therefore the standard deviation (or variance) is an appropriate measure of risk in the portfolio selection process. This is the risk measure that is used in the well-known Markowitz portfolio selection model (that is, mean-variance model), which is the foundation for modern portfolio theory. Mounting evidence since the early 1960s strongly suggests that return distributions do not follow a normal distribution, but instead exhibit heavy tails and, possibly, skewness. The “tails” of the distribution are where the extreme values occur, and these extreme values are more likely than would be predicted by the normal distribution. This means that between periods where the market exhibits relatively modest changes in prices and returns, there will be periods where there are changes that are much higher (that is, crashes and booms) than predicted by the normal distribution. This is of major concern to financial modelers in seeking to generate probability estimates for financial risk assessment. To more effectively implement portfolio selection, researchers have proposed alternative risk measures. These risk measures fall into

two disjointed categories: dispersion measures and safety-first measures. Dispersion measures include mean standard deviation, mean absolute deviation, mean absolute moment, index of dissimilarity, mean entropy, and mean colog. Safety-first risk measures include classical safety first, value-at-risk, average value-at-risk, expected tail loss, MiniMax, lower partial moment, downside risk, probability-weighted function of deviations below a specified target return, and power conditional value-at-risk. Despite these alternative risk measures, the most popular risk measure used in financial modeling is volatility as measured by the standard deviation. There are different types of volatility: historical, implied volatility, level-dependent volatility, local volatility, and stochastic volatility (e.g., jump-diffusion volatility). There are risk measures commonly used for bond portfolio management. These measures include duration, convexity, key rate duration, and spread duration.

Software for Financial Modeling

The development of financial models requires the modeler to be familiar with spreadsheets such as Microsoft Excel and/or a platform to implement concepts and algorithms such as the Palisade Decision Tools Suite and other Excel-based software (mostly @RISK1, Solver2, VBA3), and MATLAB. Financial modelers can choose one or the other, depending on their level of familiarity and comfort with spreadsheet programs and their add-ins versus programming environments such as MATLAB. Some tasks and implementations are easier in one environment than in the other. MATLAB is a modeling environment that allows for input and output processing, statistical analysis, simulation, and other types of model building for the purpose of analysis of a situation. MATLAB uses a number-array-oriented programming language, that is, a programming language in which vectors and matrices

are the basic data structures. Reliable built-in functions, a wide range of specialized toolboxes, easy interface with widespread software like Microsoft Excel, and beautiful graphing capabilities for data visualization make implementation with MATLAB efficient and useful for the financial modeler. Visual Basic for Applications (VBA) is a programming language environment that allows Microsoft Excel users to automate tasks, create their own functions, perform complex calculations, and interact with spreadsheets. VBA shares many of the same concepts as object-oriented programming languages. Despite some important limitations, VBA does add useful capabilities to spreadsheet modeling, and it is a good tool to know because Excel is the platform of choice for many finance professionals.

Stochastic Processes and Tools

Stochastic integration provides a coherent way to represent that instantaneous uncertainty (or volatility) cumulates over time. It is thus fundamental to the representation of financial processes such as interest rates, security prices, or cash flows. Stochastic integration operates on stochastic processes and produces random variables or other stochastic processes. Stochastic integration is a process defined on each path as the limit of a sum. However, these sums are different from the sums of the Riemann-Lebesgue integrals because the paths of stochastic processes are generally not of bounded variation. Stochastic integrals in the sense of Itô are defined through a process of approximation by (1) defining Brownian motion, which is the continuous limit of a random walk, (2) defining stochastic integrals for elementary functions as the sums of the products of the elementary functions multiplied by the increments of the Brownian motion, and (3) extending this definition to any function through approximating sequences. The major application of integration to financial modeling involves stochastic

integrals. An understanding of stochastic integrals is needed to understand an important tool in contingent claims valuation: stochastic differential equations. The dynamic of financial asset returns and prices can be expressed using a deterministic process if there is no uncertainty about its future behavior, or, with a stochastic process, in the more likely case when the value is uncertain. Stochastic processes in continuous time are the most used tool to explain the dynamic of financial assets returns and prices. They are the building blocks to construct financial models for portfolio optimization, derivatives pricing, and risk management. Continuous-time processes allow for more elegant theoretical modeling compared to discrete time models, and many results proven in probability theory can be applied to obtain a simple evaluation method.

Statistics

Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). In statistics, probabilistic models are applied using data so as to estimate the parameters of these models. It is not assumed that all parameter values in the model are known. Instead, the data for the variables in the model to estimate the value of the parameters are used and then applied to test hypotheses or make inferences about their estimated values. In financial modeling, the statistical technique of regression models is the workhorse. However, because regression models are part of the field of financial econometrics, this topic is covered in that topic category. Understanding dependences or functional links between variables is a key theme in

financial modeling. In general terms, functional dependencies are represented by dynamic models. Many important models are linear models whose coefficients are correlation coefficients. In many instances in financial modeling, it is important to arrive at a quantitative measure of the strength of dependencies. The correlation coefficient provides such a measure. In many instances, however, the correlation coefficient might be misleading. In particular, there are cases of nonlinear dependencies that result in a zero correlation coefficient. From the point of view of financial modeling, this situation is particularly dangerous as it leads to substantially underestimated risk. Different measures of dependence have been proposed, in particular copula functions. The copula overcomes the drawbacks of the correlation as a measure of dependency by allowing for a more general measure than linear dependence, allowing for the modeling of dependence for extreme events, and being indifferent to continuously increasing transformations. Another essential tool in financial modeling, because it allows the incorporation of uncertainty in financial models and consideration of additional layers of complexity that are difficult to incorporate in analytical models, is Monte Carlo simulation. The main idea of Monte Carlo simulation is to represent the uncertainty in market variables through scenarios, and to evaluate parameters of interest that depend on these market variables in complex ways. The advantage of such an approach is that it can easily capture the dynamics of underlying processes and the otherwise complex effects of interactions among market variables. A substantial amount of research in recent years has been dedicated to making scenario generation more accurate and efficient, and a number of sophisticated computational techniques are now available to the financial modeler.

Term Structure Modeling

The arbitrage-free valuation approach to the valuation of option-free bonds, bonds with em-

bedded options, and option-type derivative instruments requires that a financial instrument be viewed as a package of zero-coupon bonds. Consequently, in financial modeling, it is essential to be able to discount each expected cash flow by the appropriate interest rate. That rate is referred to as the spot rate. The term structure of interest rates provides the relationship between spot rates and maturity. Because of its role in valuation of cash bonds and option-type derivatives, the estimation of the term structure of interest rates is of critical importance as an input into a financial model. In addition to its role in valuation modeling, term structure models are fundamental to expressing value, risk, and establishing relative value across the spectrum of instruments found in the various interest-rate or bond markets. The term structure is most often specified for a specific market such as the U.S. Treasury market, the bond market for double-A rated financial institutions, the interest rate market for LIBOR, and swaps. Static models of the term structure are characterizations that are devoted to relationships based on a given market and do not serve future scenarios where there is uncertainty. Standard static models include those known as the spot yield curve, discount function, par yield curve, and the implied forward curve. Instantiations of these models may be found in both a discrete- and continuous-time framework. An important consideration is establishing how these term structure models are constructed and how to transform one model into another. In modeling the behavior of interest rates, stochastic differential equations (SDEs) are commonly used. The SDEs used to model interest rates must capture the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates. For a one-factor model, the SDE is used to model the behavior of the short-term rate, referred to as simply the "short rate." The addition of another factor (i.e., a two-factor model) involves extending the SDE to represent the behavior of the short rate and a long-term rate (i.e., long rate).

The entries can serve as material for a wide spectrum of courses, such as the following:

- Financial engineering
- Financial mathematics
- Financial econometrics
- Statistics with applications in finance
- Quantitative asset management
- Asset and derivative pricing
- Risk management

Frank J. Fabozzi
Editor, *Encyclopedia of Financial Models*

Guide to the *Encyclopedia of Financial Models*

The *Encyclopedia of Financial Models* provides comprehensive coverage of the field of financial modeling. This reference work consists of three separate volumes and 127 entries. Each entry provides coverage of the selected topic intended to inform a broad spectrum of readers ranging from finance professionals to academicians to students to fiduciaries. To derive the greatest possible benefit from the *Encyclopedia of Financial Models*, we have provided this guide. It explains how the information within the encyclopedia can be located.

ORGANIZATION

The *Encyclopedia of Financial Models* is organized to provide maximum ease of use for its readers.

Table of Contents

A complete table of contents for the entire encyclopedia appears in the front of each volume. This list of titles represents topics that have been carefully selected by the editor, Frank J. Fabozzi. The Preface includes a more detailed description of the volumes and the topic categories that the entries are grouped under.

Index

A Subject Index for the entire encyclopedia is located at the end of each volume. The sub-

jects in the index are listed alphabetically and indicate the volume and page number where information on this topic can be found.

Entries

Each entry in the *Encyclopedia of Financial Models* begins on a new page, so that the reader may quickly locate it. The author's name and affiliation are displayed at the beginning of the entry. All entries in the encyclopedia are organized according to a standard format, as follows:

- Title and author
- Abstract
- Introduction
- Body
- Key points
- Notes
- References

Abstract

The abstract for each entry gives an overview of the topic, but not necessarily the content of the entry. This is designed to put the topic in the context of the entire *Encyclopedia*, rather than give an overview of the specific entry content.

Introduction

The text of each entry begins with an introductory section that defines the topic under

discussion and summarizes the content. By reading this section, the reader gets a general idea about the content of a specific entry.

Body

The body of each entry explains the purpose, theory, and math behind each model.

Key Points

The key points section provides in bullet point format a review of the materials discussed in

each entry. It imparts to the reader the most important issues and concepts discussed.

Notes

The notes provide more detailed information and citations of further readings.

References

The references section lists the publications cited in the entry.

Abstract: The theory of portfolio selection together with capital asset pricing theory provides the foundation and the building blocks for the management of portfolios. The goal of portfolio selection is the construction of portfolios that maximize expected returns consistent with individually acceptable levels of risk. Using both historical data and investor expectations of future returns, portfolio selection uses modeling techniques to quantify expected portfolio returns and acceptable levels of portfolio risk and provides methods to select an optimal portfolio.

The theory of portfolio selection presented in this entry, often referred to as *mean-variance portfolio analysis* or simply mean-variance analysis, is a normative theory. A normative theory is one that describes a standard or norm of behavior that investors should pursue in constructing a portfolio rather than a prediction concerning actual behavior.

Asset pricing theory goes on to formalize the relationship that should exist between asset returns and risk if investors behave in a hypothesized manner. In contrast to a normative

theory, asset pricing theory is a positive theory—a theory that hypothesizes how investors behave rather than how investors should behave. Based on that hypothesized behavior of investors, a model that provides the expected return (a key input for constructing portfolios based on mean-variance analysis) is derived and is called an asset pricing model.

Together, portfolio selection theory and asset pricing theory provide a framework to specify and measure investment risk and to develop relationships between expected asset return and

risk (and hence between risk and required return on an investment). However, it is critically important to understand that portfolio selection is a theory that is independent of any theories about asset pricing. The validity of portfolio selection theory does not rest on the validity of asset pricing theory.

It would not be an overstatement to say that modern portfolio theory has revolutionized the world of investment management. Allowing managers to quantify the investment risk and expected return of a portfolio has provided the scientific and objective complement to the subjective art of investment management. More importantly, whereas at one time the focus of portfolio management used to be the risk of individual assets, the theory of portfolio selection has shifted the focus to the risk of the entire portfolio. This theory shows that it is possible to combine risky assets and produce a portfolio whose expected return reflects its components, but with considerably lower risk. In other words, it is possible to construct a portfolio whose risk is smaller than the sum of all its individual parts!

Though practitioners realized that the risks of individual assets were related, before modern portfolio theory, they were unable to formalize how combining these assets into a portfolio impacted the risk at the entire portfolio level, or how the addition of a new asset would change the return–risk characteristics of the portfolio. This is because practitioners were unable to quantify the returns and risks of their investments. Furthermore, in the context of the entire portfolio, they were also unable to formalize the interaction of the returns and risks across asset classes and individual assets. The failure to quantify these important measures and formalize these important relationships made the goal of constructing an optimal portfolio highly subjective and provided no insight into the return investors could expect and the risk they were undertaking. The other drawback before the advent of the theory of portfolio selection and asset pricing theory was that there was no mea-

surement tool available to investors for judging the performance of their investment managers.

SOME BASIC CONCEPTS

Portfolio theory draws on concepts from two fields: financial economic theory and probability and statistical theory. This section presents the concepts from financial economic theory used in portfolio theory. While many of the concepts presented here have a more technical or rigorous definition, the purpose is to keep the explanations simple and intuitive so that the importance and contribution of these concepts to the development of modern portfolio theory can be appreciated.

Utility Function and Indifference Curves

There are many situations where entities (i.e., individuals and firms) face two or more choices. The economic “theory of choice” uses the concept of a utility function to describe the way entities make decisions when faced with a set of choices. A utility function assigns a (numeric) value to all possible choices faced by the entity. The higher the value of a particular choice, the greater the utility derived from that choice. The choice that is selected is the one that results in the maximum utility given a set of constraints faced by the entity.

In portfolio theory too, entities are faced with a set of choices. Different portfolios have different levels of expected return and risk. Typically, the higher the level of expected return, the larger the risk. Entities are faced with the decision of choosing a portfolio from the set of all possible risk–return combinations, where when they like return, they dislike risk. Therefore, entities obtain different levels of utility from different risk–return combinations. The utility obtained from any possible risk–return combination is expressed by the utility function. Put simply, the utility function expresses the

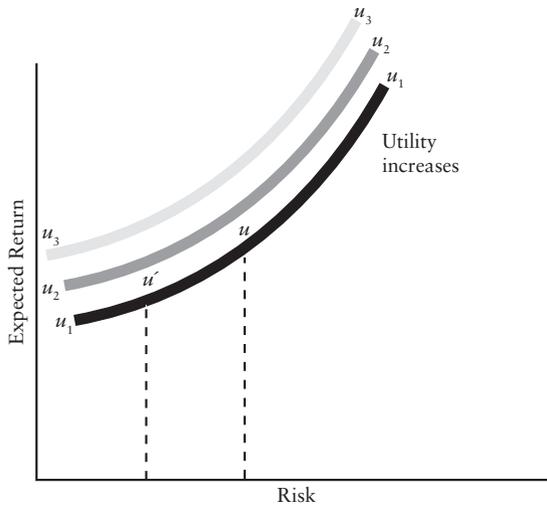

Figure 1 Indifference Curves

preferences of entities over perceived risk and expected return combinations.

A utility function can be expressed in graphical form by a set of indifference curves. Figure 1 shows indifference curves labeled u_1 , u_2 , and u_3 . By convention, the horizontal axis measures risk and the vertical axis measures expected return. Each curve represents a set of portfolios with different combinations of risk and return. All the points on a given indifference curve indicate combinations of risk and expected return that will give the same level of utility to a given investor. For example, on utility curve u_1 , there are two points u and u' , with u having a higher expected return than u' , but also having a higher risk. Because the two points lie on the same indifference curve, the investor has an equal preference for (or is indifferent to) the two points, or, for that matter, any point on the curve. The (positive) slope of an indifference curve reflects the fact that, to obtain the same level of utility, the investor requires a higher expected return in order to accept higher risk.

For the three indifference curves shown in Figure 1, the utility the investor receives is greater the further the indifference curve is from the horizontal axis because that curve represents a higher level of return at every level

of risk. Thus, for the three indifference curves shown in the figure, u_3 has the highest utility and u_1 the lowest.

The Set of Efficient Portfolios and the Optimal Portfolio

Portfolios that provide the largest possible expected return for given levels of risk are called *efficient portfolios*. To construct an efficient portfolio, it is necessary to make some assumption about how investors behave when making investment decisions. One reasonable assumption is that investors are risk averse. A risk-averse investor is an investor who, when faced with choosing between two investments with the same expected return but two different risks, prefers the one with the lower risk.

In selecting portfolios, an investor seeks to maximize the expected portfolio return given his tolerance for risk. (Alternatively stated, an investor seeks to minimize the risk that he is exposed to given some target expected return.) Given a choice from the set of efficient portfolios, an *optimal portfolio* is the one that is most preferred by the investor.

Risky Assets vs. Risk-Free Assets

A risky asset is one for which the return that will be realized in the future is uncertain. For example, an investor who purchases the stock of Pfizer Corporation today with the intention of holding it for some finite time does not know what return will be realized at the end of the holding period. The return will depend on the price of Pfizer's stock at the time of sale and on the dividends that the company pays during the holding period. Thus, Pfizer stock, and indeed the stock of all companies, is a risky asset.

Securities issued by the U.S. government are also risky. For example, an investor who purchases a U.S. government bond that matures in 30 years does not know the return that will be realized if this bond is held for only one year. This is because changes in interest rates in that year will affect the price of the bond one year

from now and that will impact the return on the bond over that year.

There are assets, however, for which the return that will be realized in the future is known with certainty today. Such assets are referred to as risk-free or riskless assets. The risk-free asset is commonly defined as a short-term obligation of the U.S. government. For example, if an investor buys a U.S. government security that matures in one year and plans to hold that security for one year, then there is no uncertainty about the return that will be realized. The investor knows that in one year, the maturity date of the security, the government will pay a specific amount to retire the debt. Notice how this situation differs for the U.S. government security that matures in 30 years. While the 1-year and the 30-year securities are obligations of the U.S. government, the former matures in one year so that there is no uncertainty about the return that will be realized. In contrast, while the investor knows what the government will pay at the end of 30 years for the 30-year bond, he does not know what the price of the bond will be one year from now.

MEASURING A PORTFOLIO'S EXPECTED RETURN

We are now ready to define the actual and expected return of a risky asset and a portfolio of risky assets.

Measuring Single-Period Portfolio Return

The actual return on a portfolio of assets over some specific time period is straightforward to calculate using the formula:

$$R_p = w_1 R_1 + w_2 R_2 + \dots + w_G R_G \quad (1)$$

where

R_p = rate of return on the portfolio over the period

R_g = rate of return on asset g over the period

w_g = weight of asset g in the portfolio (i.e., market value of asset g as a proportion of the market value of the total portfolio) at the beginning of the period

G = number of assets in the portfolio

In shorthand notation, equation (1) can be expressed as follows:

$$R_p = \sum_{g=1}^G w_g R_g \quad (2)$$

Equation (2) states that the return on a portfolio (R_p) of G assets is equal to the sum over all individual assets' weights in the portfolio times their respective return. The portfolio return R_p is sometimes called the holding period return or the ex post return.

For example, consider the following portfolio consisting of three assets:

Asset	Market Value at the Beginning of Holding Period	Rate of Return over Holding Period
1	\$6 million	12%
2	\$8 million	10%
3	\$11 million	5%

The portfolio's total market value at the beginning of the holding period is \$25 million. Therefore,

$$w_1 = \$6 \text{ million} / \$25 \text{ million} = 0.24, \text{ or } 24\% \text{ and } R_1 = 12\%$$

$$w_2 = \$8 \text{ million} / \$25 \text{ million} = 0.32, \text{ or } 32\% \text{ and } R_2 = 10\%$$

$$w_3 = \$11 \text{ million} / \$25 \text{ million} = 0.44, \text{ or } 44\% \text{ and } R_3 = 5\%$$

Notice that the sum of the weights is equal to 1. Substituting into equation (1), we get the holding period portfolio return,

$$R_p = 0.24(12\%) + 0.32(10\%) + 0.44(5\%) = 8.28\%$$

The Expected Return of a Portfolio of Risky Assets

Equation (1) shows how to calculate the actual return of a portfolio over some specific time period. In portfolio management, the investor also

wants to know the expected (or anticipated) return from a portfolio of risky assets. The expected portfolio return is the weighted average of the expected return of each asset in the portfolio. The weight assigned to the expected return of each asset is the percentage of the market value of the asset to the total market value of the portfolio. That is,

$$E(R_p) = w_1 E(R_1) + w_2 E(R_2) + \dots + w_G E(R_G) \quad (3)$$

The $E()$ signifies expectations, and $E(R_p)$ is sometimes called the *ex ante* return, or the expected portfolio return over some specific time period.

The expected return, $E(R_i)$, on a risky asset i is calculated as follows. First, a probability distribution for the possible rates of return that can be realized must be specified. A probability distribution is a function that assigns a probability of occurrence to all possible outcomes for a random variable. Given the probability distribution, the expected value of a random variable is simply the weighted average of the possible outcomes, where the weight is the probability associated with the possible outcome.

In our case, the random variable is the uncertain return of asset i . Having specified a probability distribution for the possible rates of return, the expected value of the rate of return for asset i is the weighted average of the possible outcomes. Finally, rather than use the term “expected value of the return of an asset,” we simply use the term “expected return.” Mathematically, the expected return of asset i is expressed as

$$E(R_i) = p_1 R_1 + p_2 R_2 + \dots + p_N R_N \quad (4)$$

where

R_n = the n th possible rate of return for asset i

p_n = the probability of attaining the rate of return R_n for asset i

N = the number of possible outcomes for the rate of return

How do we specify the probability distribution of returns for an asset? We shall see later

Table 1 Probability Distribution for the Rate of Return for Stock XYZ

n	Rate of Return	Probability of Occurrence
1	12%	0.18
2	10%	0.24
3	8%	0.29
4	4%	0.16
5	-4%	0.13
Total		1.00

on in this entry that in most cases the probability distribution of returns is based on long-run historical returns. If there is no reason to believe that future long-run returns should differ significantly from historical long-run returns, then probabilities assigned to different return outcomes based on the historical long-run performance of an uncertain investment could be a reasonable estimate for the probability distribution. However, for the purpose of illustration, assume that an investor is considering an investment, stock XYZ, which has a probability distribution for the rate of return for some time period as given in Table 1. The stock has five possible rates of return and the probability distribution specifies the likelihood of occurrence (in a probabilistic sense) of each of the possible outcomes.

Substituting into equation (4) we get

$$\begin{aligned} E(R_{XYZ}) &= 0.18(12\%) + 0.24(10\%) + 0.29(8\%) \\ &\quad + 0.16(4\%) + 0.13(-4\%) \\ &= 7\% \end{aligned}$$

Thus, 7% is the expected return or mean of the probability distribution for the rate of return on stock XYZ.

MEASURING PORTFOLIO RISK

Investors have used a variety of definitions to describe risk. Markowitz (1952, 1959) quantified the concept of risk using the well-known statistical measure: the standard deviation and the variance. The former is the intuitive concept. For most probability density functions, about

95% of the outcomes fall in the range defined by two standard deviations above and below the mean. Variance is defined as the square of the standard deviation. Computations are simplest in terms of variance. Therefore, it is convenient to compute the variance of a portfolio and then take its square root to obtain standard deviation.

Variance and Standard Deviation as a Measure of Risk

The variance of a random variable is a measure of the dispersion or variability of the possible outcomes around the expected value (mean). In the case of an asset's return, the variance is a measure of the dispersion of the possible rate of return outcomes around the expected return.

The equation for the variance of the expected return for asset i , denoted $\text{var}(R_i)$, is

$$\text{var}(R_i) = p_1[r_1 - E(R_i)]^2 + p_2[r_2 - E(R_i)]^2 + \dots + p_N[r_N - E(R_i)]^2$$

or

$$\text{var}(R_i) = \sum_{n=1}^N p_n[r_n - E(R_i)]^2 \quad (5)$$

Using the probability distribution of the return for stock XYZ, we can illustrate the calculation of the variance:

$$\begin{aligned} \text{var}(R_{XYZ}) &= 0.18(12\% - 7\%)^2 + 0.24(10\% - 7\%)^2 \\ &\quad + 0.29(8\% - 7\%)^2 + 0.16(4\% - 7\%)^2 \\ &\quad + 0.13(-4\% - 7\%)^2 = 24.1\% \end{aligned}$$

The variance associated with a distribution of returns measures the tightness with which the distribution is clustered around the mean or expected return. Markowitz argued that this tightness or variance is equivalent to the uncertainty or riskiness of the investment. If an asset is riskless, it has an expected return dispersion of zero. In other words, the return (which is also the expected return in this case) is certain, or guaranteed.

Since the variance is squared units, as we know from earlier in this section, it is common to see the variance converted to the standard deviation by taking the positive square root:

$$SD(R_i) = \sqrt{\text{Var}(R_i)}$$

For stock XYZ, then, the standard deviation is

$$SD(R_{XYZ}) = \sqrt{24.1\%} = 4.9\%$$

The variance and standard deviation are conceptually equivalent; that is, the larger the variance or standard deviation, the greater the investment risk. (A criticism of the variance or standard deviation as a measure is discussed later in this entry.)

Measuring the Portfolio Risk of a Two-Asset Portfolio

Equation (5) gives the variance for an individual asset's return. The variance of a portfolio consisting of two assets is a little more difficult to calculate. It depends not only on the variance of the two assets, but also upon how closely the returns of one asset track those of the other asset. The formula is

$$\begin{aligned} \text{var}(R_p) &= w_i^2 \text{var}(R_i) + w_j^2 \text{var}(R_j) \\ &\quad + 2w_i w_j \text{cov}(R_i, R_j) \end{aligned} \quad (6)$$

where

$\text{cov}(R_i, R_j)$ = covariance between the return for assets i and j

In words, equation (6) states that the variance of the portfolio return is the sum of the squared weighted variances of the two assets plus two times the weighted covariance between the two assets. We will see that this equation can be generalized to the case where there are more than two assets in the portfolio.

Covariance

The covariance has a precise mathematical translation. Its practical meaning is the degree to which the returns of two assets covary or change together. The covariance is not expressed in a particular unit, such as dollars or percent. A positive covariance means the returns on two assets tend to move or change in

Table 2 Probability Distribution for the Rate of Return for Asset XYZ and Asset ABC

<i>n</i>	Rate of Return for Asset XYZ	Rate of Return for Asset ABC	Probability of Occurrence
1	12%	21%	0.18
2	10%	14%	0.24
3	8%	9%	0.29
4	4%	4%	0.16
5	-4%	-3%	0.13
Total			1.00
Expected return	7.0%	10.0%	
Variance	24.1%	53.6%	
Standard deviation	4.9%	7.3%	

the same direction, while a negative covariance means the returns tend to move in opposite directions. The covariance between any two assets *i* and *j* is computed using the following formula:

$$\begin{aligned} \text{cov}(R_i, R_j) = & p_1[r_{i1} - E(R_i)][r_{j1} - E(R_j)] \\ & + p_2[r_{i2} - E(R_i)][r_{j2} - E(R_j)] + \dots \\ & + p_N[r_{iN} - E(R_i)][r_{jN} - E(R_j)] \end{aligned} \quad (7)$$

where

- r_{in} = the *n*th possible rate of return for asset *i*
- r_{jn} = the *n*th possible rate of return for asset *j*
- p_n = the probability of attaining the rate of return r_{in} and r_{jn} for assets *i* and *j*
- N = the number of possible outcomes for the rate of return

To illustrate the calculation of the covariance between two assets, we use the two stocks in Table 2. The first is stock XYZ from Table 1 that we used earlier to illustrate the calculation of the expected return and the standard deviation. The other hypothetical stock is stock ABC, whose data are shown in Table 2. Substituting the data for the two stocks from Table 2 in equation (7), the covariance between stocks XYZ and ABC is calculated as follows:

$$\begin{aligned} \text{cov}(R_{XYZ}, R_{ABC}) &= 0.18(12\% - 7\%)(21\% - 10\%) \\ &+ 0.24(10\% - 7\%)(14\% - 10\%) + 0.29(8\% \\ &- 7\%)(9\% - 10\%) + 0.16(4\% - 7\%)(4\% - 10\%) \\ &+ 0.13(-4\% - 7\%)(-3\% - 10\%) = 0.3396\% \end{aligned}$$

Relationship between Covariance and Correlation

The correlation is related to the covariance between the expected returns for two assets. Specifically, the correlation between the returns for assets *i* and *j* is defined as the covariance of the two assets divided by the product of their standard deviations:

$$\text{cor}(R_i, R_j) = \text{cov}(R_i, R_j) / [SD(R_i)SD(R_j)] \quad (8)$$

Dividing the covariance between the returns of two assets by the product of their standard deviations results in the correlation between the returns of the two assets. Because the correlation is a standardized number (i.e., it has been corrected for differences in the standard deviation of the returns), the correlation is comparable across different assets. The correlation between the returns for stock XYZ and stock ABC is

$$\text{cor}(R_{XYZ}, R_{ABC}) = 0.3396\% / (4.9\% \times 7.3\%) \approx 0.95$$

The correlation coefficient can have values ranging from +1.0, denoting perfect comovement in the same direction, to -1.0, denoting perfect comovement in the opposite direction. Also note that because the standard deviations are always positive, the correlation can only be negative if the covariance is a negative number. A correlation of zero implies that the returns are uncorrelated.

Measuring the Risk of a Portfolio Consisting of More than Two Assets

So far we have defined the risk of a portfolio consisting of two assets. The extension to three assets—*i*, *j*, and *k*—is as follows:

$$\begin{aligned} \text{var}(R_p) = & w_i^2 \text{var}(R_i) + w_j^2 \text{var}(R_j) + w_k^2 \text{var}(R_k) \\ & + 2w_i w_j \text{cov}(R_i, R_j) + 2w_i w_k \text{cov}(R_i, R_k) \\ & + 2w_j w_k \text{cov}(R_j, R_k) \end{aligned} \quad (9)$$

In words, equation (9) states that the variance of the portfolio return is the sum of the squared weighted variances of the individual assets plus two times the sum of the weighted pairwise

covariances of the assets. In general, for a portfolio with G assets, the portfolio variance is given by

$$\begin{aligned} \text{var}(R_p) = & \sum_{g=1}^G w_g^2 \text{var}(R_g) \\ & + \sum_{\substack{g=1 \\ \text{and} \\ h \neq g}}^G \sum_{h=1}^G w_g w_h \text{cov}(R_g, R_h) \end{aligned} \quad (10)$$

PORTFOLIO DIVERSIFICATION

Often, one hears investors talking about diversifying their portfolio. By this an investor means constructing a portfolio in such a way as to reduce portfolio risk without sacrificing return. This is certainly a goal that investors should seek. However, the question is how to do this in practice.

Some investors would say that including assets across all asset classes could diversify a portfolio. For example, a investor might argue that a portfolio should be diversified by investing in stocks, bonds, and real estate. While that might be reasonable, two questions must be addressed in order to construct a diversified portfolio. First, how much should be invested in each asset class? Should 40% of the portfolio be in stocks, 50% in bonds, and 10% in real estate, or is some other allocation more appropriate? Second, given the allocation, which specific stocks, bonds, and real estate should the investor select?

Some investors who focus only on one asset class such as common stock argue that such portfolios should also be diversified. By this they mean that an investor should not place all funds in the stock of one corporation, but rather should include stocks of many corporations. Here, too, several questions must be answered in order to construct a diversified portfolio. First, which corporations should be represented in the portfolio? Second, how much

of the portfolio should be allocated to the stocks of each corporation?

Prior to the development of portfolio theory, while investors often talked about diversification in these general terms, they did not possess the analytical tools by which to answer the questions posed above. For example, in 1945, Leavens (1945, p. 473) wrote:

An examination of some fifty books and articles on investment that have appeared during the last quarter of a century shows that most of them refer to the desirability of diversification. The majority, however, discuss it in general terms and do not clearly indicate why it is desirable.

Leavens illustrated the benefits of diversification on the assumption that risks are independent. However, in the last paragraph of his article, he cautioned:

The assumption, mentioned earlier, that each security is acted upon by independent causes, is important, although it cannot always be fully met in practice. Diversification among companies in one industry cannot protect against unfavorable factors that may affect the whole industry; additional diversification among industries is needed for that purpose. Nor can diversification among industries protect against cyclical factors that may depress all industries at the same time.

A major contribution of the theory of portfolio selection is that using the concepts discussed above, a quantitative measure of the diversification of a portfolio is possible, and it is this measure that can be used to achieve the maximum diversification benefits.

The Markowitz diversification strategy is primarily concerned with the degree of covariance between asset returns in a portfolio. Indeed a key contribution of Markowitz diversification is the formulation of an asset's risk in terms of a portfolio of assets, rather than in isolation. Markowitz diversification seeks to combine assets in a portfolio with returns that are less than perfectly positively correlated, in an effort to lower portfolio risk (variance) without sacrificing return. It is the concern for maintaining return while lowering risk through an analysis of the covariance between asset returns that separates Markowitz diversification from a naive

approach to diversification and makes it more effective.

Markowitz diversification and the importance of asset correlations can be illustrated with a simple two-asset portfolio example. To do this, we first show the general relationship between the risk of a two-asset portfolio and the correlation of returns of the component assets. Then we look at the effects on portfolio risk of combining assets with different correlations.

Portfolio Risk and Correlation

In our two-asset portfolio, assume that asset C and asset D are available with expected returns and standard deviations as shown:

Asset	$E(R)$	$SD(R)$
Asset C	12%	30%
Asset D	18%	40%

If an equal 50% weighting is assigned to both stocks C and D, the expected portfolio return can be calculated as shown:

$$E(R_p) = 0.50(12\%) + 0.50(18\%) = 15\%$$

The variance of the return on the two-stock portfolio from equation (6), using decimal form rather than percentage form for the standard deviation inputs, is

$$\begin{aligned} \text{var}(R_p) &= w_C^2 \text{var}(R_C) + w_D^2 \text{var}(R_D) \\ &\quad + 2w_C w_D \text{cov}(R_C, R_D) \\ &= (0.5)^2(0.30)^2 + (0.5)^2(0.40)^2 \\ &\quad + 2(0.5)(0.5) \text{cov}(R_C, R_D) \end{aligned}$$

From equation (8),

$$\text{cor}(R_C, R_D) = \text{cov}(R_C, R_D) / [SD(R_C)SD(R_D)]$$

so

$$\text{cov}(R_C, R_D) = SD(R_C)SD(R_D)\text{cor}(R_C, R_D)$$

Since $SD(R_C) = 0.30$ and $SD(R_D) = 0.40$, then

$$\text{cov}(R_C, R_D) = (0.30)(0.40) \text{cor}(R_C, R_D)$$

Substituting into the expression for $\text{var}(R_p)$, we get

$$\begin{aligned} \text{var}(R_p) &= (0.5)^2(0.30)^2 + (0.5)^2(0.40)^2 \\ &\quad + 2(0.5)(0.5)(0.30)(0.40)\text{cor}(R_C, R_D) \end{aligned}$$

Taking the square root of the variance gives

$$\begin{aligned} SD(R_p) &= \sqrt{(0.5)^2(0.30)^2 + (0.5)^2(0.40)^2 \\ &\quad + 2(0.5)(0.5)(0.30)(0.40)\text{cor}(R_C, R_D)} \\ &= \sqrt{0.0625 + (0.06)\text{cor}(R_C + R_D)} \end{aligned} \tag{11}$$

The Effect of the Correlation of Asset Returns on Portfolio Risk

How would the risk change for our two-asset portfolio with different correlations between the returns of the component stocks? Let's consider the following three cases for $\text{cor}(R_C, R_D)$: +1.0, 0, and -1.0. Substituting into equation (11) for these three cases of $\text{cor}(R_C, R_D)$, we get:

$\text{cor}(R_C, R_D)$	$E(R_p)$	$SD(R_p)$
+1.0	15%	35%
0.0	15%	25%
-1.0	15%	5%

As the correlation between the expected returns on stocks C and D decreases from +1.0 to 0.0 to -1.0, the standard deviation of the expected portfolio return also decreases from 35% to 5%. However, the expected portfolio return remains 15% for each case.

This example clearly illustrates the effect of Markowitz diversification. The principle of Markowitz diversification states that as the correlation (covariance) between the returns for assets that are combined in a portfolio decreases, so does the variance (hence the standard deviation) of the return for the portfolio.

The good news is that investors can maintain expected portfolio return and lower portfolio risk by combining assets with lower (and preferably negative) correlations. However, the bad news is that very few assets have small

Table 3 Portfolio Expected Returns and Standard Deviations for Five Mixes of Assets C and D
 Asset C: $E(R_C) = 12\%$, $SD(R_C) = 30\%$
 Asset D: $E(R_D) = 18\%$, and $SD(R_D) = 40\%$
 Correlation between Assets C and D = $\text{cor}(R_C, R_D) = -0.5$

Portfolio	Proportion of Asset C	Proportion of Asset D	$E(R_p)$	$SD(R_p)$
1	100%	0%	12.0%	30.0%
2	75%	25%	13.5%	19.5%
3	50%	50%	15.0%	18.0%
4	25%	75%	16.5%	27.0%
5	0%	100%	18.0%	40.0%

to negative correlations with other assets! The problem, then, becomes one of searching among large numbers of assets in an effort to discover the portfolio with the minimum risk at a given level of expected return or, equivalently, the highest expected return at a given level of risk.

The stage is now set for a discussion of efficient portfolios and their construction.

CHOOSING A PORTFOLIO OF RISKY ASSETS

Diversification in the manner suggested by Markowitz leads to the construction of portfolios that have the highest expected return for a given level of risk. Such portfolios are called *efficient portfolios*.

Constructing Efficient Portfolios

The technique of constructing efficient portfolios from large groups of stocks requires a massive number of calculations. In a portfolio of G securities, there are $(G^2 - G)/2$ unique covariances to estimate. Hence, for a portfolio of just 50 securities, there are 1,225 covariances that must be calculated. For 100 securities, there are 4,950. Furthermore, in order to solve for the portfolio that minimizes risk for each level of return, a mathematical technique called quadratic programming must be used. A discussion of this technique is beyond the scope of this entry. However, it is possible to illustrate the general idea of the construction of efficient portfolios by

referring again to the simple two-asset portfolio consisting of assets C and D.

Recall that for two assets, C and D , $E(R_C) = 12\%$, $SD(R_C) = 30\%$, $E(R_D) = 18\%$, and $SD(R_D) = 40\%$. We now further assume that $\text{cor}(R_C, R_D) = -0.5$. Table 3 presents the expected portfolio return and standard deviation for five different portfolios made up of varying proportions of C and D .

Feasible and Efficient Portfolios

A feasible portfolio is any portfolio that an investor can construct given the assets available. The five portfolios presented in Table 3 are all feasible portfolios. The collection of all feasible portfolios is called the *feasible set of portfolios*. With only two assets, the feasible set of portfolios is graphed as a curve, which represents those combinations of risk and expected return that are attainable by constructing portfolios from all possible combinations of the two assets.

Figure 2 presents the feasible set of portfolios for all combinations of assets C and D. As mentioned earlier, the portfolio mixes listed in Table 3 belong to this set and are shown by the points 1 through 5, respectively. Starting from 1 and proceeding to 5, asset C goes from 100% to 0%, while asset D goes from 0% to 100%—therefore, all possible combinations of C and D lie between portfolios 1 and 5, or on the curve labeled 1–5. In the case of two assets, any risk–return combination not lying on this curve is not attainable since there is no mix of assets C and D that will result in that risk–return

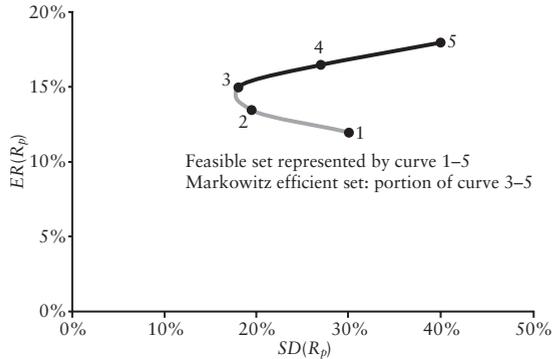

Figure 2 Feasible and Efficient Portfolios for Assets C and D

combination. Consequently, the curve 1–5 can also be thought of as the feasible set.

In contrast to a feasible portfolio, an *efficient portfolio* is one that gives the highest expected return of all feasible portfolios with the same risk. An efficient portfolio is also said to be a *mean-variance efficient portfolio*. Thus, for each level of risk there is an efficient portfolio. The collection of all efficient portfolios is called the *efficient set*.

The efficient set for the feasible set presented in Figure 2 is differentiated by the bold curve section 3–5. Efficient portfolios are the combinations of assets C and D that result in the risk–return combinations on the bold section of the curve. These portfolios offer the highest expected return at a given level of risk. Notice that two of our five portfolio mixes—portfolio 1 with $E(R_p) = 12\%$ and $SD(R_p) = 20\%$ and portfolio 2 with $E(R_p) = 13.5\%$ and $SD(R_p) = 19.5\%$ —are not included in the efficient set. This is because there is at least one portfolio in the efficient set (for example, portfolio 3) that has a higher expected return and lower risk than both of them. We can also see that portfolio 4 has a higher expected return and lower risk than portfolio 1. In fact, the whole curve section 1–3 is not efficient. For any given risk–return combination on this curve section, there is a combination (on the curve section 3–5) that has the same risk and a higher return, or the same return and a lower risk, or both. In other words, for any

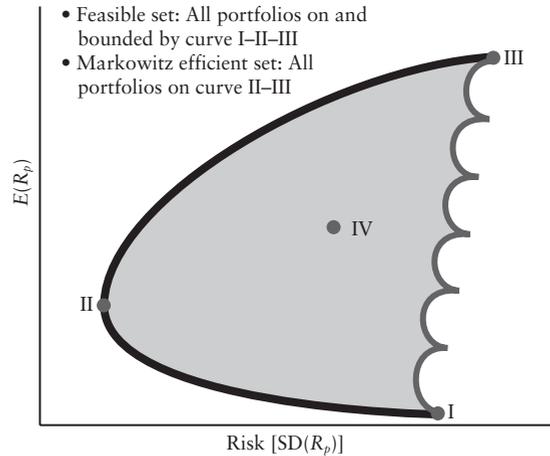

Figure 3 Feasible and Efficient Portfolios with More Than Two Assets^a

^aThe picture is for illustrative purposes only. The actual shape of the feasible region depends on the returns and risks of the assets chosen and the correlation among them.

portfolio that results in the return/risk combination on the curve section 1–3 (excluding portfolio 3), there exists a portfolio that dominates it by having the same return and lower risk, or the same risk and a higher return, or a lower risk and a higher return. For example, portfolio 4 dominates portfolio 1, and portfolio 3 dominates both portfolios 1 and 2.

Figure 3 shows the feasible and efficient sets when there are more than two assets. In this case, the feasible set is not a line, but an area. This is because, unlike the two-asset case, it is possible to create asset portfolios that result in risk–return combinations that not only result in combinations that lie on the curve I–II–III, but all combinations that lie in the shaded area. However, the efficient set is given by the curve II–III. It is easily seen that all the portfolios on the efficient set dominate the portfolios in the shaded area.

The efficient set of portfolios is sometimes called the *efficient frontier* because graphically all the efficient portfolios lie on the boundary of the set of feasible portfolios that have the maximum return for a given level of risk. Any risk–return combination above the efficient frontier cannot

be achieved, while risk–return combinations of the portfolios that make up the efficient frontier dominate those that lie below the efficient frontier.

Choosing the Optimal Portfolio in the Efficient Set

Now that we have constructed the efficient set of portfolios, the next step is to determine the optimal portfolio.

Since all portfolios on the efficient frontier provide the greatest possible return at their level of risk, an investor or entity will want to hold one of the portfolios on the efficient frontier. Notice that the portfolios on the efficient frontier represent trade-offs in terms of risk and return. Moving from left to right on the efficient frontier, the risk increases, but so does the expected return. The question is which one of those portfolios should an investor hold? The best portfolio to hold of all those on the efficient frontier is the *optimal portfolio*.

Intuitively, the optimal portfolio should depend on the investor’s preference over different risk–return trade-offs. As explained earlier, this preference can be expressed in terms of a utility function.

In Figure 4, three indifference curves representing a utility function and the efficient frontier are drawn on the same diagram. An indifference curve indicates the combinations of risk and expected return that give the same level of utility. Moreover, the farther the indifference curve from the horizontal axis, the higher the utility.

From Figure 4, it is possible to determine the optimal portfolio for the investor with the indifference curves shown. Remember that the investor wants to get to the highest indifference curve achievable given the efficient frontier. Given that requirement, the optimal portfolio is represented by the point where an indifference curve is tangent to the efficient frontier. In Figure 4, that is the portfolio P_{MEF}^* . For example, suppose that P_{MEF}^* corresponds to portfolio 4

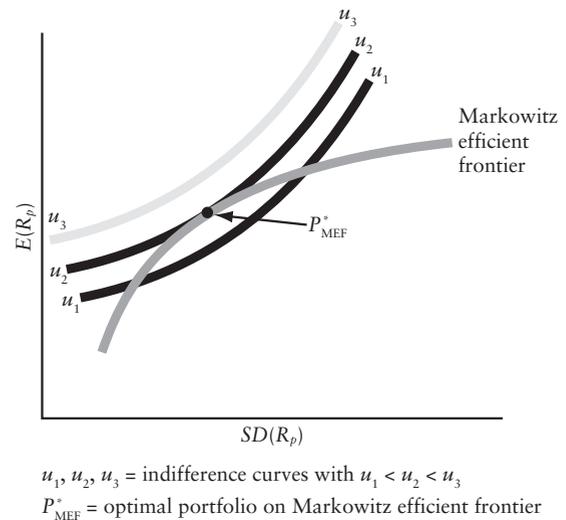

Figure 4 Selection of the Optimal Portfolio

in Figure 2. We know from Table 3 that this portfolio is made up of 25% of asset C and 75% of asset D, with an $E(R_p) = 16.5\%$ and $SD(R_p) = 27.0\%$.

Consequently, for the investor’s preferences over risk and return as determined by the shape of the indifference curves represented in Figure 4, and expectations for asset C and D inputs (returns and variance-covariance) represented in Table 3, portfolio 4 is the optimal portfolio because it maximizes the investor’s utility. If this investor had a different preference for expected risk and return, there would have been a different optimal portfolio.

At this point in our discussion, a natural question is how to estimate an investor’s utility function so that the indifference curves can be determined. Economists in the field of behavioral and experimental economics have conducted a vast amount of research in the area of utility functions. Though the assumption sounds reasonable that individuals should possess a function that maps the different preference choices they face, the research shows that it is not so straightforward to assign an individual with a specific utility function. This is because preferences may be dependent on circumstances, and those may change with time.

Table 4 Annualized Expected Returns, Standard Deviations, and Correlations between the Four Country Equity Indexes: Australia, Austria, Belgium, and Canada

Expected Returns	Standard Deviation	Correlations	1	2	3	4
7.9%	19.5%	Australia	1	1		
7.9%	18.2%	Austria	2	0.24	1	
9.0%	18.3%	Belgium	3	0.25	0.47	1
7.1%	16.5%	Canada	4	0.22	0.14	0.25
						1

The inability to assign an investor with a specific utility function does not imply that the theory is irrelevant. Once the efficient frontier is constructed, it is possible for the investor to subjectively evaluate the trade-offs for the different return–risk outcomes and choose the efficient portfolio that is appropriate given his or her tolerance to risk.

Example Using the MSCI World Country Indexes

Now that we know how to calculate the optimal portfolios and the efficient frontier, let us take a look at a practical example. We start the example using only four assets and later show these results change as more assets are included. The four assets are the four country equity indexes in the MSCI World Index for Australia, Austria, Belgium, and Canada.

Let us assume that we are given the annualized expected returns, standard deviations, and correlations between these countries as presented in Table 4. The expected returns vary from 7.1% to 9%, whereas the standard deviations range from 16.5% to 19.5%. Furthermore, we observe that the four country indexes are not highly correlated with each other—the highest correlation, 0.47, is between Austria and Belgium. Therefore, we expect to see some benefits of portfolio diversification.

Figure 5 shows the efficient frontier for the four assets. We observe that the four assets, represented by the diamond-shaped marks, are all below the efficient frontier. This means that for a targeted expected portfolio return, the mean-variance portfolio has a lower standard deviation. A utility maximizing investor, measuring

utility as the trade-off between expected return and standard deviation, will prefer a portfolio on the efficient frontier over any of the individual assets.

The portfolio at the leftmost end of the efficient frontier (marked with a solid circle in Figure 5) is the portfolio with the smallest obtainable standard deviation. It is called the *global minimum variance* (GMV) portfolio.

Increasing the Asset Universe

We know that by introducing more (low correlating) assets, for a targeted expected portfolio return, we should be able to decrease the standard deviation of the portfolio. In Table 5, the assumed annualized expected returns, stan-

standard deviations, and correlations of 18 countries in the MSCI World Index are presented.

Figure 6 illustrates how the efficient frontier moves outwards and upwards as we go from 4 to 12 assets and then to 18 assets. By increasing the number of investment opportunities, we increase the level of possible diversification thereby making it possible to generate a higher level of return at each level of risk.

Adding Short Selling Constraints

So far in this section, our theoretical derivations imposed no restrictions on the portfolio weights other than having them add up to one. In particular, we allowed the portfolio weights to take on both positive and negative values; that is, we did not restrict short selling. In practice, many portfolio managers cannot sell assets short. This could be for investment policy or legal reasons, or sometimes just because particular asset classes are difficult to sell short such real estate. In Figure 7, we see the effect of not allowing for short selling. Since we are restricting the opportunity set by constraining all the weights to be

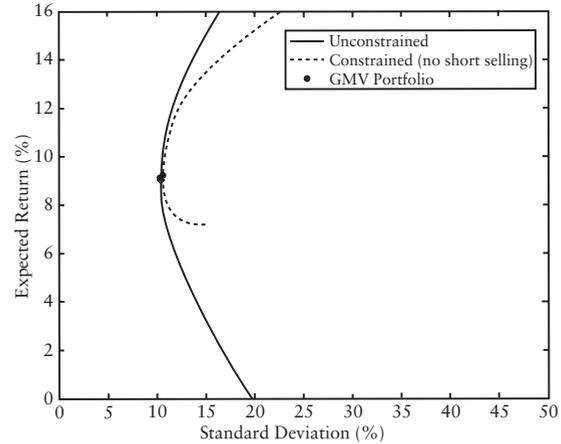

Figure 7 The Effect of Restricting Short Selling: Constrained versus Unconstrained Efficient Frontiers Constructed from 18 Countries from the MSCI World Index
Note: The portfolios on the curves above the GMV portfolio constitute the efficient frontiers.

positive, the resulting efficient frontier is inside the unconstrained efficient frontier.

ROBUST PORTFOLIO OPTIMIZATION

Despite the great influence and theoretical impact of modern portfolio theory, today full risk–return optimization at the asset level is primarily done only at the more quantitatively oriented asset management firms. The availability of quantitative tools is not the issue—today’s optimization technology is mature and much more user-friendly than it was at the time Markowitz first proposed the theory of portfolio selection—yet many asset managers avoid using the quantitative portfolio allocation framework altogether.

A major reason for the reluctance of portfolio managers to apply quantitative risk–return optimization is that they have observed that it may be unreliable in practice. Specifically, mean–variance optimization (or any measure of risk for that matter) is very sensitive to changes

in the inputs (in the case of mean-variance optimization, such inputs include the expected return and variance of each asset and the asset covariance between each pair of assets). While it can be difficult to make accurate estimates of these inputs, estimation errors in the forecasts significantly impact the resulting portfolio weights. As a result, the optimal portfolios generated by the mean-variance analysis generally have extreme or counterintuitive weights for some assets.¹ Such examples, however, are not necessarily a sign that the theory of portfolio selection is flawed; rather, that when used in practice, the mean-variance analysis as presented by Markowitz has to be modified in order to achieve reliability, stability, and robustness with respect to model and estimation errors.

It goes without saying that advances in the mathematical and physical sciences have had a major impact upon finance. In particular, mathematical areas such as probability theory, statistics, econometrics, operations research, and mathematical analysis have provided the necessary tools and discipline for the development of modern financial economics. Substantial advances in the areas of robust estimation and robust optimization were made during the 1990s, and have proven to be of great importance for the practical applicability and reliability of portfolio management and optimization.

Any statistical estimate is subject to error—that is, estimation error. A robust estimator is a statistical estimation technique that is less sensitive to outliers in the data and is not driven by one particular set of observations of the data. For example, in practice, it is undesirable that one or a few extreme returns have a large impact on the estimation of the average return of a stock. Nowadays, statistical techniques such as Bayesian analysis and robust statistics are more commonplace in asset management. Taking it one step further, practitioners are starting to incorporate the uncertainty introduced by estimation errors directly into the optimization process. This is very different from traditional mean-variance analysis, where one solves the

portfolio optimization problem as a problem with deterministic inputs (i.e., inputs that are assumed to be known with certainty), without taking the estimation errors into account. In particular, the statistical precision of individual estimates is explicitly incorporated into the portfolio allocation process. Providing this benefit is the underlying goal of robust portfolio optimization.²

Modern robust optimization techniques allow a portfolio manager to solve the robust version of the portfolio optimization problem in about the same time as needed for the traditional mean-variance portfolio optimization problem. The robust approach explicitly uses the distribution from the estimation process to find a robust portfolio in a single optimization, thereby directly incorporating uncertainty about inputs in the optimization process. As a result, robust portfolios are less sensitive to estimation errors than other portfolios, and often perform better than optimal portfolios determined by traditional mean-variance portfolios. Moreover, the robust optimization framework offers greater flexibility and many new interesting applications. For instance, robust portfolio optimization can exploit the notion of statistically equivalent portfolios. This concept is important in large-scale portfolio management involving many complex constraints such as transaction costs, turnover, or market impact. Specifically, with robust optimization, a portfolio manager can find the best portfolio that (1) minimizes trading costs with respect to the current holdings and (2) has an expected portfolio return and variance that are statistically equivalent to those of the classical mean-variance portfolio.³

KEY POINTS

- Markowitz quantified the concept of diversification through the statistical notion of the covariances between individual securities that make up a portfolio and the overall standard deviation of the portfolio.

- A basic assumption behind modern portfolio theory is that an investor's preferences over portfolios with different expected returns and variances can be represented by a function (utility function).
- The basic principle underlying modern portfolio theory is that for a given level of expected return an investor would choose the portfolio with the minimum variance from among the set of all possible portfolios.
- Minimum variance portfolios are called mean-variance efficient portfolios. The set of all mean-variance efficient portfolios is called the efficient frontier. The portfolio on the efficient frontier with the smallest variance is called the global minimum variance portfolio (GMVP).
- The efficient frontier moves outwards and upwards as the number of (not perfectly correlated) securities increases. The efficient frontier shrinks as constraints are imposed upon the portfolio.
- An advancement in the theory of portfolio selection is the development of estimation techniques that generate more robust mean-variance estimates along with optimization techniques that result in optimized portfolios being more robust to the mean-variance estimates used.

NOTES

1. See Best and Grauer (1991) and Chopra and Ziemba (1993).
2. There are two approaches that have been suggested for dealing with this problem. One is the application of estimation by using a statistical technique known as Bayes analysis. (See Rachev, Hsu, Bagasheva, and Fabozzi, 2008.) The Black-Litterman model uses this approach. (See Black and Litterman, 1990.) The other approach is using a resampling methodology as suggested by Michaud (2001). A study by Markowitz and Usmen (2003) found that the resampled approach is superior to that of a Bayesian approach.
3. For a discussion of these models, see Fabozzi, Kolm, Pachamanova, and Focardi (2007).

Abstract: The mathematical theory of optimization has a natural application in the field of finance. From a general perspective, the behavior of economic agents in the face of uncertainty involves balancing expected risks and expected rewards. For example, the portfolio choice problem concerns the optimal trade-off between risk and reward. A portfolio is said to be optimal in the sense that it is the best portfolio among many alternative ones. The criterion that measures the quality of a portfolio relative to the others is known as the objective function in optimization theory. The set of portfolios among which we are choosing is called the “set of feasible solutions” or the “set of feasible points.”

In *optimization* theory there is a distinction between two types of optimization problems depending on whether the set of feasible solutions is constrained or unconstrained. If the optimization problem is a constrained one, then the *set of feasible solutions* is defined by means of certain linear and/or nonlinear equalities and inequalities. These functions are often said to be forming the *constraint set*. Furthermore, a distinction is made between the types of optimization problems depending on the

assumed properties of the *objective function* and the functions in the constraint set, such as *linear problems*, *quadratic problems*, and *convex problems*. The solution methods vary with respect to the particular optimization problem type as there are efficient algorithms prepared for particular problem types.

In this chapter, we describe the basic types of optimization problems and remark on the methods for their solution. Boyd and Vandenberghe (2004) and Ruszczyński (2006)

provide more detailed information on the topic.

UNCONSTRAINED OPTIMIZATION

When there are no constraints imposed on the set of feasible solutions, we have an *unconstrained optimization* problem. Thus, the goal is to maximize or to minimize the objective function with respect to the function arguments without any limits on their values. We consider directly the n -dimensional case; that is, the domain of the objective function f is the n -dimensional space and the function values are real numbers, $f : \mathbb{R}^n \rightarrow \mathbb{R}$. Maximization is denoted by

$$\max f(x_1, \dots, x_n)$$

and minimization by

$$\min f(x_1, \dots, x_n)$$

A more compact form is commonly used; for example

$$\min_{x \in \mathbb{R}^n} f(x) \quad (1)$$

denotes that we are searching for the minimal value of the function $f(x)$ by varying x in the entire n -dimensional space \mathbb{R}^n . A solution to problem (1) is a value of $x = x^0$ for which the minimum of f is attained:

$$f_0 = f(x^0) = \min_{x \in \mathbb{R}^n} f(x)$$

Thus, the vector x_0 is such that the function takes a larger value than f_0 for any other vector x ,

$$f(x^0) \leq f(x), x \in \mathbb{R}^n \quad (2)$$

Note that there may be more than one vector x^0 satisfying the inequality in (2) and, therefore, the argument for which f_0 is achieved may not be unique. If (2) holds, then the function is said to attain its global minimum at x^0 . If the inequality in (2) holds for x belonging only to a small neighborhood of x^0 and not to the entire space \mathbb{R}^n , then the objective function is said to have a

local minimum at x^0 . This is usually denoted by

$$f(x^0) \leq f(x)$$

for all x such that $\|x - x^0\|_2 < \epsilon$ where $\|x - x^0\|_2$ stands for the Euclidean distance between the vectors x and x^0 ,

$$\|x - x^0\|_2 = \sqrt{\sum_{i=1}^n (x_i - x_i^0)^2}$$

and ϵ is some positive number. A local minimum may not be global as there may be vectors outside the small neighborhood of x_0 for which the objective function attains a smaller value than $f(x_0)$. Figure 3 shows the graph of a function with two local maxima, one of which is the global maximum.

There is a connection between minimization and maximization. Maximizing the objective function is the same as minimizing the negative of the objective function and then changing the sign of the minimal value:

$$\max_{x \in \mathbb{R}^n} f(x) = -\min_{x \in \mathbb{R}^n} [-f(x)]$$

This relationship is illustrated in Figure 1. As a consequence, problems for maximization can be stated in terms of function minimization and vice versa.

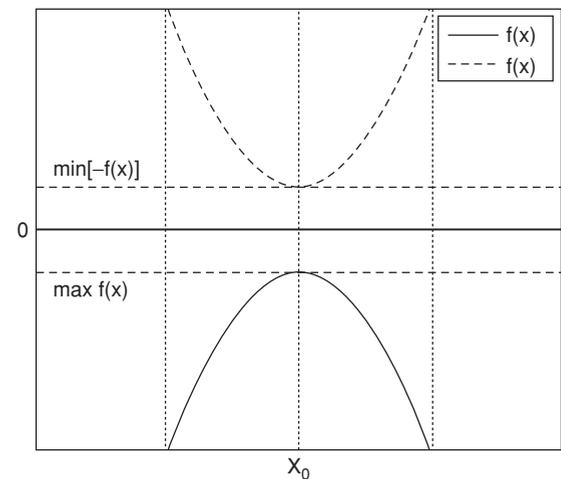

Figure 1 The Relationship between Minimization and Maximization for a One-Dimensional Function

Minima and Maxima of a Differentiable Function

If the second derivatives of the objective function exist, then its local maxima and minima, often called generically local extrema, can be characterized. Denote by $\nabla f(x)$ the vector of the first partial derivatives of the objective function evaluated at x ,

$$\nabla f(x) = \left(\frac{\partial f(x)}{\partial x_1}, \dots, \frac{\partial f(x)}{\partial x_n} \right)$$

This vector is called the function gradient. At each point x of the domain of the function, it shows the direction of greatest rate of increase of the function in a small neighborhood of x . If for a given x the gradient equals a vector of zeros,

$$\nabla f(x) = (0, \dots, 0)$$

then the function does not change in a small neighborhood of $x \in \mathbb{R}^n$. It turns out that all points of local extrema of the objective function are characterized by a zero gradient. As a result, the points yielding the local extrema of the objective function are among the solutions of the system of equations,

$$\begin{cases} \frac{\partial f(x)}{\partial x_1} = 0 \\ \dots \\ \frac{\partial f(x)}{\partial x_n} = 0 \end{cases} \quad (3)$$

The system of equations (3) is often referred to as representing the first-order condition for the objective function extrema. However, it is only a necessary condition; that is, if the gradient is zero at a given point in the n -dimensional space, then this point may or may not be a point of a local extremum for the function. An illustration is given in Figures 2 and 3. Figure 2 shows the graph of a two-dimensional function and Figure 3 contains the contour lines of the function with the gradient calculated at a grid of points. There are three points marked with a black dot which have a zero gradient. The middle point is not a point of a local maximum even though it has a zero gradient. This point is called a *sad-*

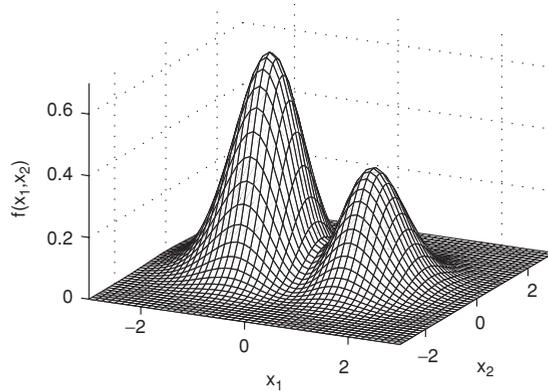

Figure 2 A Function $f(x_1, x_2)$ with Two Local Maxima

dle point, since the graph resembles the shape of a saddle in a neighborhood of it. The left and the right points are where the function has two local maxima corresponding to the two peaks visible on the top plot. The right peak is a local maximum which is not the global one and the left peak represents the global maximum.

This example demonstrates that the first-order conditions are generally insufficient to characterize the points of local extrema. The additional condition which identifies which of the

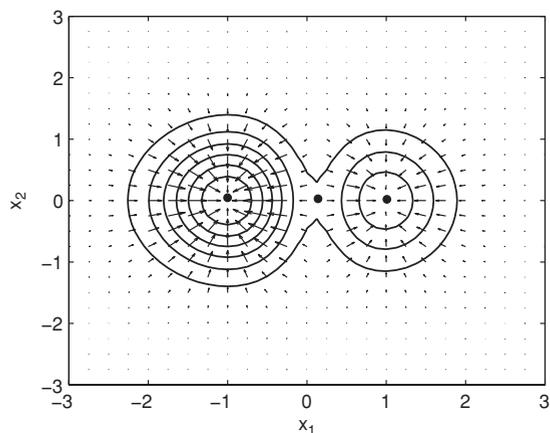

Figure 3 The Contour Lines of $f(x_1, x_2)$ Together with the Gradient Evaluated at a Grid of Points

Note: The middle black point shows the position of the saddle point between the two local maxima.

zero-gradient points are points of local minimum or maximum is given through the matrix of second derivatives,

$$H = \begin{pmatrix} \frac{\partial^2 f(x)}{\partial x_1^2} & \frac{\partial^2 f(x)}{\partial x_1 \partial x_2} & \cdots & \frac{\partial^2 f(x)}{\partial x_1 \partial x_n} \\ \frac{\partial^2 f(x)}{\partial x_2 \partial x_1} & \frac{\partial^2 f(x)}{\partial x_2^2} & \cdots & \frac{\partial^2 f(x)}{\partial x_2 \partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial^2 f(x)}{\partial x_n \partial x_1} & \frac{\partial^2 f(x)}{\partial x_n \partial x_2} & \cdots & \frac{\partial^2 f(x)}{\partial x_n^2} \end{pmatrix} \quad (4)$$

which is called the Hessian matrix or just the Hessian. The Hessian is a symmetric matrix because the order of differentiation is insignificant:

$$\frac{\partial^2 f(x)}{\partial x_i \partial x_j} = \frac{\partial^2 f(x)}{\partial x_j \partial x_i}$$

The additional condition is known as the second-order condition. We will not provide the second-order condition for functions of n -dimensional arguments because it is rather technical and goes beyond the scope of the entry. We only state it for two-dimensional functions.

In the case $n = 2$, the following conditions hold:

- If $\nabla f(x_1, x_2) = (0, 0)$ at a given point (x_1, x_2) and the determinant of the Hessian matrix evaluated at (x_1, x_2) is positive, then the function has:

A local maximum in (x_1, x_2) if

$$\frac{\partial^2 f(x_1, x_2)}{\partial x_1^2} < 0 \quad \text{or} \quad \frac{\partial^2 f(x_1, x_2)}{\partial x_2^2} < 0$$

A local minimum in (x_1, x_2) if

$$\frac{\partial^2 f(x_1, x_2)}{\partial x_1^2} > 0 \quad \text{or} \quad \frac{\partial^2 f(x_1, x_2)}{\partial x_2^2} > 0$$

- If $\nabla f(x_1, x_2) = (0, 0)$ at a given point (x_1, x_2) and the determinant of the Hessian matrix evaluated at (x_1, x_2) is negative, then the function f has a saddle point in (x_1, x_2) .
- If $\nabla f(x_1, x_2) = (0, 0)$ at a given point (x_1, x_2) and the determinant of the Hessian matrix evaluated at (x_1, x_2) is zero, then no conclusion can be drawn.

Convex Functions

We just demonstrated that the first-order conditions are insufficient in the general case to describe the local extrema. However, when certain assumptions are made for the objective function, the first-order conditions can become sufficient. Furthermore, for certain classes of functions, the local extrema are necessarily global. Therefore, solving the first-order conditions we obtain the global extremum.

A general class of functions with nice *optimal* properties is the class of *convex functions*. Not only are the convex functions easy to optimize but also they have important application in risk management. (See Chapter 6 in Rachev, Stoyanov, and Fabozzi [2008] for a discussion of general measures of risk.) It turns out that the property which guarantees that diversification is possible appears to be exactly the convexity property. As a consequence, a measure of risk is necessarily a convex functional.

A *function* in mathematics can be viewed as a rule assigning to each element of a set D a single element of a set C . The set D is called the domain of f and the set C is called the codomain of f . A *functional* is a special kind of a function which takes other functions as its argument and returns numbers as output; that is, its domain is a set of functions. For example, the definite integral can be viewed as a functional because it assigns a real number to a function—the corresponding area below the function graph. A risk measure can also be viewed as a functional because it assigns a number to a random variable. Any random variable is mathematically described as a certain function the domain of which is a set of outcomes Ω .

Precisely, a function $f(x)$ is called a convex function if it satisfies the property: For a given $\alpha \in [0, 1]$ and all $x^1 \in \mathbb{R}^n$ and $x^2 \in \mathbb{R}^n$ in the function domain,

$$f(\alpha x^1 + (1 - \alpha)x^2) \leq \alpha f(x^1) + (1 - \alpha)f(x^2) \quad (5)$$

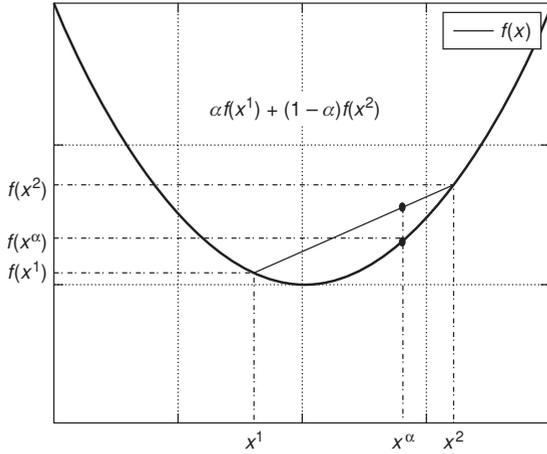

Figure 4 Illustration of the Definition of a Convex Function in the One-Dimensional Case
 Note: On the plot, $x_\alpha = \alpha x^1 + (1 - \alpha)x^2$.

The definition is illustrated in Figure 4. Basically, if a function is convex, then a straight line connecting any two points on the graph lies “above” the graph of the function.

There is a related term to convex functions. A function f is called *concave* if the negative of f is convex. In effect, a function is concave if it satisfies the property: For a given $\alpha \in [0, 1]$ and all $x^1 \in \mathbb{R}^n$ and $x^2 \in \mathbb{R}^n$ in the function domain,

$$f(\alpha x^1 + (1 - \alpha)x^2) \geq \alpha f(x^1) + (1 - \alpha)f(x^2)$$

If the domain D of a convex function is not the entire space \mathbb{R}^n , then the set D satisfies the property

$$\alpha x^1 + (1 - \alpha)x^2 \in D \quad (6)$$

where $x^1 \in D$, $x^2 \in D$, and $0 \leq \alpha \leq 1$. The sets which satisfy (6) are called convex sets. Thus, the domains of convex (and concave) functions should be convex sets. Geometrically, a set is convex if it contains the straight line connecting any two points belonging to the set. Rockafellar (1997) provides detailed information on the implications of convexity in optimization theory.

We summarize several important properties of convex functions:

- Not all convex functions are differentiable. If a convex function is two times continuously differentiable, then the corresponding Hessian defined in (4) is a positive semidefinite matrix. (A matrix H is a positive semidefinite matrix if $x'Hx \geq 0$ for all $x \in \mathbb{R}^n$ and $x \neq (0, \dots, 0)$.)
- All convex functions are continuous if considered in an open set.
- The sublevel sets

$$L_c = \{x : f(x) \leq c\} \quad (7)$$

where c is a constant, are convex sets if f is a convex function. The converse is not true in general. Later, we provide more information about nonconvex functions with convex sublevel sets.

- The local minima of a convex function are global. If a convex function f is twice continuously differentiable, then the global minimum is obtained in the points solving the first-order condition

$$\nabla f(x) = 0$$

- A sum of convex functions is a convex function:

$$f(x) = f_1(x) + f_2(x) + \dots + f_k(x)$$

if $f_i, i = 1, \dots, k$ are convex functions.

A simple example of a convex function is the linear function

$$f(x) = a'x, \quad x \in \mathbb{R}^n$$

where $a \in \mathbb{R}^n$ is a vector of constants. In fact, the linear function is the only function which is both convex and concave. In finance, if we consider a portfolio of assets, then the expected portfolio return is a linear function of portfolio weights, in which the coefficients equal the expected asset returns.

As a more involved example, consider the following function:

$$f(x) = \frac{1}{2}x'Cx, \quad x \in \mathbb{R}^n \quad (8)$$

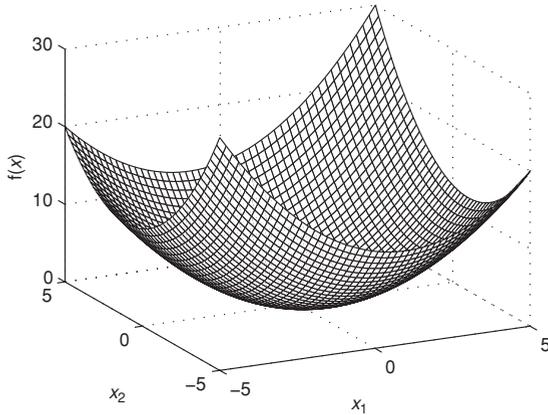

Figure 5 The Surface of a Two-Dimensional Convex Quadratic Function

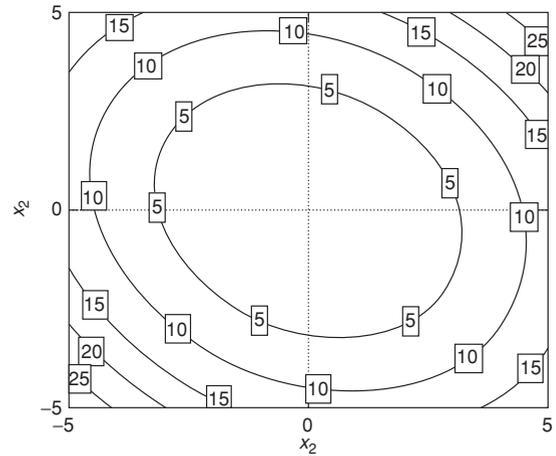

Figure 6 The Contour Lines of a Two-Dimensional Convex Quadratic Function

where $C = \{c_{ij}\}_{i,j=1}^n$ is an $n \times n$ symmetric matrix. In portfolio theory, the variance of portfolio return is a similar function of portfolio weights. In this case, C is the covariance matrix. The function defined in (8) is called a quadratic function because writing the definition in terms of the components of the argument X , we obtain

$$f(x) = \frac{1}{2} \left[\sum_{i=1}^n c_{ii} x_i^2 + \sum_{i \neq j} c_{ij} x_i x_j \right]$$

which is a quadratic function of the components $x_i, i = 1, \dots, n$. The function in (8) is convex if and only if the matrix C is positive semidefinite. In fact, in this case the matrix C equals the Hessian matrix, $C = H$. Since the matrix C contains all parameters, we say that the quadratic function is defined by the matrix C .

Figures 5–8 illustrate the surface and contour lines of a convex and nonconvex two-dimensional quadratic function. The contour lines of the convex function are concentric ellipses and a sublevel set L_c is represented by the points inside some ellipse. The point $(0, 0)$ in Figure 8 is a saddle point. The convex quadratic function is defined by the matrix

$$C = \begin{pmatrix} 1 & 0.4 \\ 0.4 & 1 \end{pmatrix}$$

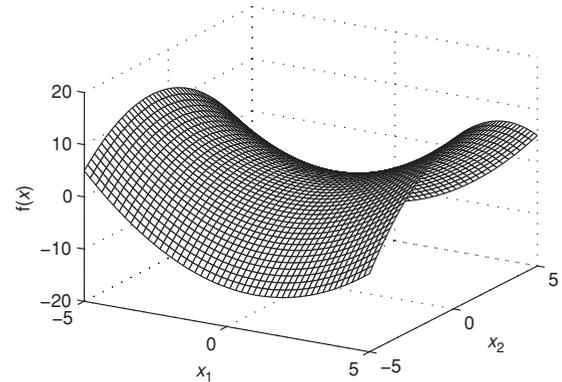

Figure 7 The Surface of a Nonconvex Two-Dimensional Quadratic Function

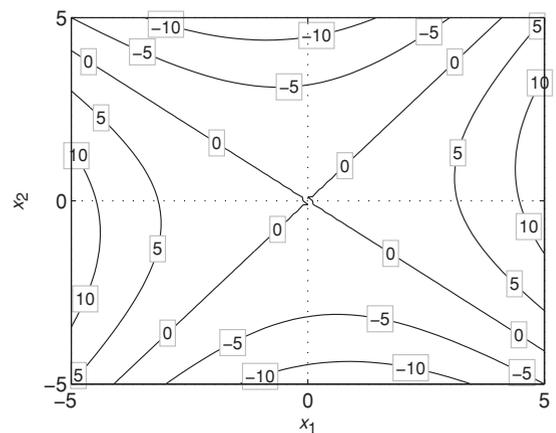

Figure 8 The Contour Lines of a Nonconvex Two-Dimensional Quadratic Function

and the nonconvex quadratic function is defined by the matrix

$$C = \begin{pmatrix} -1 & 0.4 \\ 0.4 & 1 \end{pmatrix}$$

A property of convex functions is that the sum of convex functions is a convex function. As a result of the preceding analysis, the function

$$f(x) = \lambda x' C x - a' x \tag{9}$$

where $\lambda > 0$ and C is a positive semidefinite matrix, is a convex function as a sum of two convex functions. In the mean-variance efficient frontier, as formulated by Markowitz (1952), we find functions similar to (9). Let us use the properties of convex functions in order to solve the unconstrained problem of minimizing the function in (9):

$$\min_{x \in \mathbb{R}^n} \lambda x' C x - a' x$$

This function is differentiable and we can search for the global minimum by solving the first-order conditions:

$$\nabla f(x) = 2\lambda C x - a = 0$$

Therefore, the value of x minimizing the objective function equals

$$x^0 = \frac{1}{2\lambda} C^{-1} a$$

where C^{-1} denotes the inverse of the matrix C .

Quasi-Convex Functions

Besides convex functions, there are other classes of functions with convenient optimal properties. An example of such a class is the class of *quasi-convex functions*. Formally, a function is called quasi-convex if all sublevel sets defined in (7) are convex sets. Alternatively, a function $f(x)$ is called quasi-convex if

$$f(x^1) \geq f(x^2) \text{ implies } f(\alpha x^1 + (1 - \alpha)x^2) \leq f(x^1)$$

where x^1 and x^2 belong to the function domain, which should be a convex set, and $0 \leq \alpha \leq 1$.

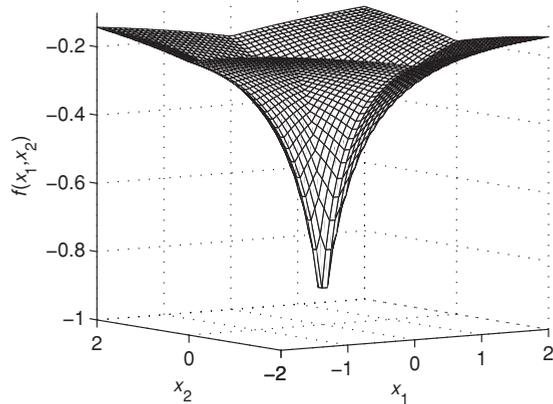

Figure 9 Example of a Two-Dimensional Quasi-Convex Function

A function f is called *quasi-concave* if $-f$ is quasi-convex.

An illustration of a two-dimensional quasi-convex function is given in Figure 9. It shows the graph of the function and Figure 10 illustrates the contour lines. A sublevel set is represented by all points inside some contour line. From a geometric viewpoint, the sublevel sets corresponding to the plotted contour lines are convex because any of them contains the straight line connecting any two points belonging to the set. Nevertheless, the function is not convex, which becomes evident from the surface in Figure 9. It is not guaranteed that a

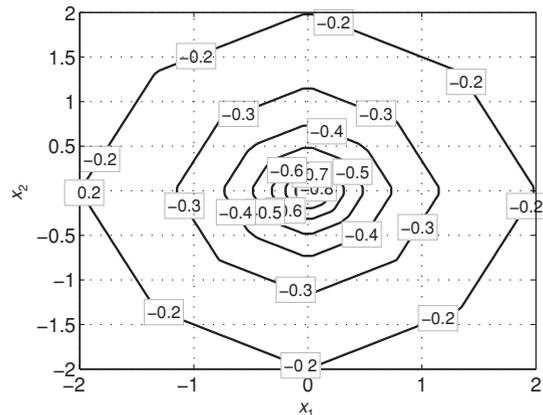

Figure 10 The Contour Lines of a Two-Dimensional Quasi-Convex Function

straight line connecting any two points on the surface will remain “above” the surface.

Properties of the quasi-convex functions include:

- Any convex function is also quasi-convex. The converse is not true, which is demonstrated in Figure 10.
- In contrast to the differentiable convex functions, the first-order condition is not necessary and sufficient for optimality in the case of differentiable quasi-convex functions. (There exists a class of functions larger than the class of convex functions but smaller than the class of quasi-convex functions, for which the first-order condition is necessary and sufficient for optimality. This is the class of pseudo-convex functions. Mangasarian [2006] provides more detail on the optimal properties of pseudo-convex functions.)
- It is possible to find a sequence of convex optimization problems yielding the global minimum of a quasi-convex function. Boyd and Vandenberghe (2004) provide further details. Its main idea is to find the smallest value of c for which the corresponding sublevel set L_c is nonempty. The minimal value of c is the global minimum, which is attained in the points belonging to the sublevel set L_c .
- Suppose that $g(x) > 0$ is a concave function and $f(x) > 0$ is a convex function. Then the ratio $g(x)/f(x)$ is a quasi-concave function and the ratio $f(x)/g(x)$ is a quasi-convex function.

Quasi-convex functions arise naturally in risk management when considering optimization of performance ratios. (See Chapter 10 in Rachev, Stoyanov, and Fabozzi [2008].)

CONSTRAINED OPTIMIZATION

In constructing optimization problems solving practical issues, it is very often the case that certain constraints need to be imposed in or-

der for the optimal solution to make practical sense. For example, long-only portfolio optimization problems require that the portfolio weights, which represent the variables in optimization, should be nonnegative and should sum up to one. According to the notation in this chapter, this corresponds to a problem of the type

$$\begin{aligned} \min_x \quad & f(x) \\ \text{subject to} \quad & x'e = 1 \\ & x \geq 0 \end{aligned} \quad (10)$$

where

$$\begin{aligned} f(x) &= \text{the objective function} \\ e \in \mathbb{R}^n &= \text{a vector of ones, } e = (1, \dots, 1) \\ x'e &= \text{the sum of all components of } x, \\ x'e &= \sum_i^n x_i \\ x \geq 0 &= \text{all components of the vector } x \in \mathbb{R}^n \\ &\text{are nonnegative} \end{aligned}$$

In problem (10), we are searching for the minimum of the objective function by varying x only in the set

$$\mathbf{X} = \left\{ x \in \mathbb{R}^n : \begin{array}{l} x'e = 1 \\ x \geq 0 \end{array} \right\} \quad (11)$$

which is also called the *set of feasible points* or the *constraint set*. A more compact notation, similar to the notation in the unconstrained problems, is sometimes used,

$$\min_{x \in \mathbf{X}} f(x)$$

where \mathbf{X} is defined in (11).

We distinguish between different types of optimization problems depending on the assumed properties for the objective function and the constraint set. If the constraint set contains only equalities, the problem is easier to handle analytically. In this case, the method of *Lagrange multipliers* is applied. For more general constraint sets, when they are formed by both equalities and inequalities, the method of Lagrange multipliers is generalized by the Karush-Kuhn-Tucker conditions (KKT conditions). Like the first-order conditions we considered in unconstrained optimization problems,

none of the two approaches lead to necessary and sufficient conditions for constrained optimization problems without further assumptions. One of the most general frameworks in which the KKT conditions are necessary and sufficient is that of *convex programming*. We have a convex programming problem if the objective function is a convex function and the *set of feasible points* is a convex set. As important subcases of convex optimization, *linear programming* and *convex quadratic programming* problems are considered.

In this section, we describe first the method of Lagrange multipliers, which is often applied to special types of mean-variance optimization problems in order to obtain closed-form solutions. Then we proceed with convex programming, which is the framework for reward-risk analysis.

Lagrange Multipliers

Consider the following optimization problem in which the set of feasible points is defined by a number of equality constraints:

$$\begin{aligned} \min_x \quad & f(x) \\ \text{subject to} \quad & h_1(x) = 0 \\ & h_2(x) = 0 \\ & \dots \\ & h_k(x) = 0 \end{aligned} \tag{12}$$

The functions $h_i(x)$, $i = 1, \dots, k$ build up the constraint set. Note that even though the right-hand side of the equality constraints is zero in the classical formulation of the problem given in (12), this is not restrictive. If in a practical problem the right-hand side happens to be different from zero, it can be equivalently transformed; for example:

$$\{x \in \mathbb{R}^n : v(x) = c\} \iff \{x \in \mathbb{R}^n : h_1(x) = v(x) - c = 0\}$$

In order to illustrate the necessary condition for optimality valid for (12), let us consider the

following two-dimensional example:

$$\begin{aligned} \min_{x \in \mathbb{R}^2} \quad & \frac{1}{2}x'Cx \\ \text{subject to} \quad & x'e = 1 \end{aligned} \tag{13}$$

where the matrix is

$$C = \begin{pmatrix} 1 & 0.4 \\ 0.4 & 1 \end{pmatrix}$$

The objective function is a quadratic function and the constraint set contains one linear equality. A mean-variance optimization problem in which short positions are allowed is very similar to (13). (See Chapter 8 in Rachev, Stoyanov, and Fabozzi [2008].) The surface of the objective function and the constraint are shown in Figures 11 and 12. The black line on the surface shows the function values of the feasible points. Geometrically, solving problem (13) reduces to finding the lowest point of the black curve on the surface. The contour lines shown in Figure 12 imply that the feasible point yielding the minimum of the objective function is where a contour line is tangential to the line defined by the equality constraint. On the plot, the tangential contour line and the feasible points are in bold. The black dot indicates the position of the point in which the objective function attains its minimum subject to the constraints.

Even though the example is not general in the sense that the constraint set contains one linear

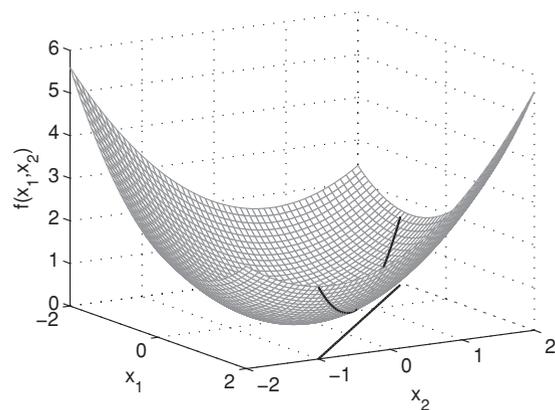

Figure 11 The Surface of a Two-Dimensional Quadratic Objective Function and the Linear Constraint $x_1 + x_2 = 1$

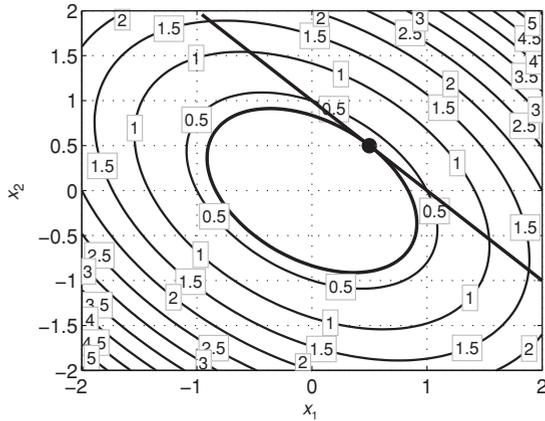

Figure 12 The Tangential Contour Line to the Linear Constraint $x_1 + x_2 = 1$

rather than a nonlinear equality, the same geometric intuition applies in the nonlinear case. The fact that the minimum is attained where a contour line is tangential to the curve defined by the nonlinear equality constraints in mathematical language is expressed in the following way: The gradient of the objective function at the point yielding the minimum is proportional to a linear combination of the gradients of the functions defining the constraint set. Formally, this is stated as:

$$\nabla f(x^0) - \mu_1 \nabla h_1(x^0) - \dots - \mu_k \nabla h_k(x^0) = 0 \quad (14)$$

where μ_i , $i = 1, \dots, k$ are some real numbers called *Lagrange multipliers* and the point x^0 is such that $f(x^0) \leq f(x)$ for all x which are feasible. Note that if there are no constraints in the problem, then (14) reduces to the first-order condition we considered in unconstrained optimization. Therefore, the system of equations behind (14) can be viewed as a generalization of the first-order condition in the unconstrained case.

The method of a Lagrange multipliers basically associates a function to the problem in (12) such that the first-order condition for unconstrained optimization for that function coincides with (14). The method of a Lagrange multiplier consists of the following steps.

1. Given the problem in (12), construct the following function:

$$L(x, \mu) = f(x) - \mu_1 h_1(x) - \dots - \mu_k h_k(x) \quad (15)$$

where $\mu = (\mu_1, \dots, \mu_k)$ is the vector of Lagrange multipliers. The function $L(x, \mu)$ is called the *Lagrangian* corresponding to problem (12).

2. Calculate the partial derivatives with respect to all components of x and μ and set them equal to zero:

$$\frac{\partial L(x, \mu)}{\partial x_i} = \frac{\partial f(x)}{\partial x_i} - \sum_{j=1}^k \mu_j \frac{\partial h_j(x)}{\partial x_i} = 0, \quad i = 1, \dots, n \quad (16)$$

$$\frac{\partial L(x, \mu)}{\partial \mu_m} = h_m(x) = 0, \quad m = 1, \dots, k$$

Basically, the system of equations (16) corresponds to the first-order conditions for unconstrained optimization written for the Lagrangian as a function of both x and μ , $L : \mathbb{R}^{n+k} \rightarrow \mathbb{R}$.

3. Solve the system of equalities in (16) for x and μ . Note that even though we are solving the first-order condition for unconstrained optimization of $L(x, \mu)$, the solution (x^0, μ^0) of (16) is not a point of local minimum or maximum of the Lagrangian. In fact, the solution (x^0, μ^0) is a saddle point of the Lagrangian.

The first n equations in (16) make sure that the relationship between the gradients given in (14) is satisfied. The following k equations in (16) make sure that the points are feasible. As a result, all vectors x solving (16) are feasible and the gradient condition is satisfied at them. Therefore, the points that solve the optimization problem (12) are among the solutions of the system of equations given in (16).

This analysis suggests that the method of Lagrange multipliers provides a necessary condition for optimality. Under certain assumptions for the objective function and the functions building up the constraint set, (16) turns out to be a necessary and sufficient condition. For

example, if $f(x)$ is a convex and differentiable function and $h_i(x)$, $i = 1, \dots, k$ are affine functions, then the method of Lagrange multipliers identifies the points solving (12). A function $h(x)$ is called affine if it has the form $h(x) = a + c'x$, where a is a constant and $c = (c_1, \dots, c_n)$ is a vector of coefficients. All linear functions are affine. Figure 12 illustrates a convex quadratic function subject to a linear constraint. In this case, the solution point is unique.

Convex Programming

The general form of convex programming problems is

$$\begin{aligned} \min_x \quad & f(x) \\ \text{subject to} \quad & g_i(x) \leq 0, \quad i = 1, \dots, m \\ & h_j(x) = 0, \quad j = 1, \dots, k \end{aligned} \quad (17)$$

where

- $f(x)$ is a convex objective function
- $g_1(x), \dots, g_m(x)$ are convex functions defining the inequality constraints
- $h_1(x), \dots, h_k(x)$ are affine functions defining the equality constraints

Generally, without the assumptions of convexity, problem (17) is more involved than (12) because besides the equality constraints, there are inequality constraints. The KKT condition, generalizing the method of Lagrange multipliers, is only a necessary condition for optimality in this case. However, adding the assumption of convexity makes the KKT condition necessary and sufficient.

Note that, similar to problem (12), the fact that the right-hand side of all constraints is zero is nonrestrictive. The limits can be arbitrary real numbers.

Consider the following two-dimensional optimization problem

$$\begin{aligned} \min_{x \in \mathbb{R}^2} \quad & \frac{1}{2}x'Cx \\ \text{subject to} \quad & (x_1 + 2)^2 + (x_2 + 2)^2 \leq 3 \end{aligned} \quad (18)$$

in which

$$C = \begin{pmatrix} 1 & 0.4 \\ 0.4 & 1 \end{pmatrix}$$

The objective function is a two-dimensional convex quadratic function and the function in the constraint set is also a convex quadratic function. In fact, the boundary of the feasible set is a circle with a radius of $\sqrt{3}$ centered at the point with coordinates $(-2, -2)$. Figures 13 and 14 show the surface of the objective function and the set of feasible points. The shaded part on the surface indicates the function values of all feasible points. In fact, solving problem (18) reduces to finding the lowest point on the shaded part of the surface. Figure 14 shows the contour lines of the objective function together with the feasible set, which is in gray. Geometrically, the point in the feasible set yielding the minimum of the objective function is positioned where a contour line only touches the constraint set. The position of this point is marked with a black dot and the tangential contour line is given in bold.

Note that the solution points of problems of the type (18) can happen to be not on the boundary of the feasible set but in the interior. For example, suppose that the radius of the circle defining the boundary of the feasible set in (18) is a larger number such that the point $(0, 0)$ is

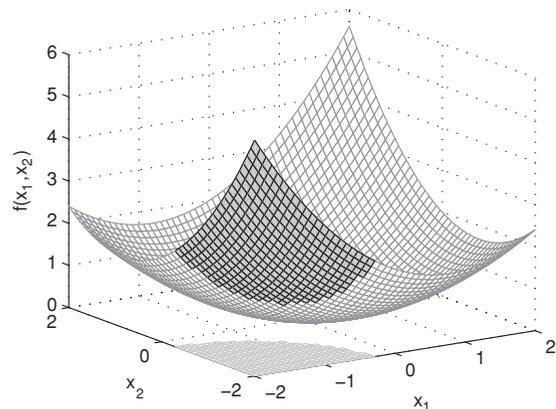

Figure 13 The Surface of a Two-Dimensional Convex Quadratic Function and a Convex Quadratic Constraint

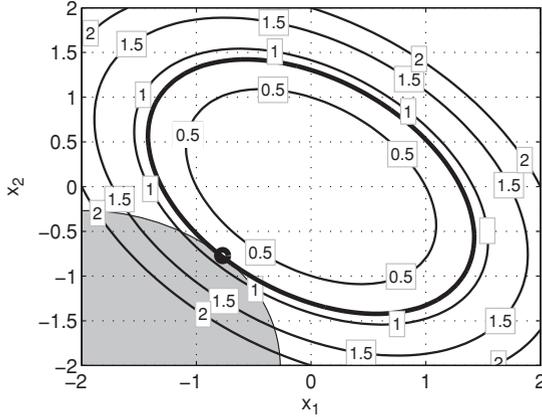

Figure 14 The Tangential Contour Line to the Feasible Set Defined by a Convex Quadratic Constraint

inside the feasible set. Then, the point $(0, 0)$ is the solution to problem (18) because at this point the objective function attains its global minimum.

In the two-dimensional case, when we can visualize the optimization problem, geometric reasoning guides us to finding the optimal solution point. In a higher dimensional space, plots cannot be produced and we rely on the analytic method behind the KKT conditions. The KKT conditions corresponding to the convex programming problem (17) are the following:

$$\begin{aligned} \nabla f(x) + \sum_{i=1}^m \lambda_i \nabla g_i(x) + \sum_{j=1}^k \mu_j \nabla h_j(x) &= 0 \\ g_i(x) &\leq 0 \quad i = 1, \dots, m \\ h_j(x) &= 0 \quad j = 1, \dots, k \\ \lambda_i g_i(x) &= 0, \quad i = 1, \dots, m \\ \lambda_i &\geq 0, \quad i = 1, \dots, m \end{aligned} \quad (19)$$

A point x^0 such that (x^0, λ^0, μ^0) satisfies (19) is the solution to problem (17). Note that if there are no inequality constraints, then the KKT conditions reduce to (16) in the method of Lagrange multipliers. Therefore, the KKT conditions generalize the method of Lagrange multipliers.

The gradient condition in (19) has the same interpretation as the gradient condition in the

method of Lagrange multipliers. The set of constraints

$$\begin{aligned} g_i(x) &\leq 0 \quad i = 1, \dots, m \\ h_j(x) &= 0 \quad j = 1, \dots, k \end{aligned}$$

guarantee that a point satisfying (19) is feasible. The next conditions

$$\lambda_i g_i(x) = 0, \quad i = 1, \dots, m$$

are called complementary slackness conditions. If an inequality constraint is satisfied as a strict inequality, then the corresponding multiplier λ_i turns into zero according to the complementary slackness conditions. In this case, the corresponding gradient $\nabla g_i(x)$ has no significance in the gradient condition. This reflects the fact that the gradient condition concerns only the constraints satisfied as equalities at the solution point.

Important special cases of convex programming problems include linear programming problems and convex quadratic programming problems, which we consider in the remaining part of this section.

Linear Programming

Optimization problems are said to be linear programming problems if the objective function is a linear function and the feasible set is defined by linear equalities and inequalities. Since all functions are linear, they are also convex, which means that linear programming problems are also convex problems. The definition of linear programming problems in standard form is the following:

$$\begin{aligned} \min_x \quad & c'x \\ \text{subject to} \quad & Ax \leq b \\ & x \geq 0 \end{aligned} \quad (20)$$

where A is an $m \times n$ matrix of coefficients, $c = (c_1, \dots, c_n)$ is a vector of objective function coefficients, and $b = (b_1, \dots, b_m)$ is a vector of real numbers. As a result, the constraint set contains m inequalities defined by linear functions. The feasible points defined by means of linear

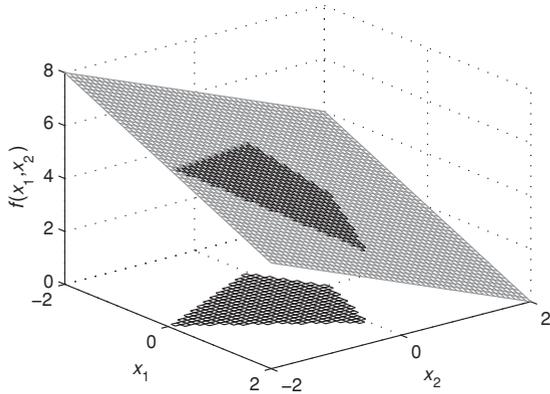

Figure 15 The Surface of a Linear Function and a Polyhedral Feasible Set

equalities and inequalities are also said to form a polyhedral set. In practice, before solving a linear programming problem, it is usually first reformulated in the standard form given in (20).

Figures 15 and 16 show an example of a two-dimensional linear programming problem which is not in standard form as the two variables may become negative. Figure 15 contains the surface of the objective function, which is a plane in this case, and the polyhedral set of feasible points. The shaded area on the surface corresponds to the points in the feasible set. Solving problem (20) reduces to finding the

lowest point in the shaded area on the surface. Figure 16 shows the feasible set together with the contour lines of the objective function. The contour lines are parallel straight lines because the objective function is linear. The point in which the objective function attains its minimum is marked with a black dot.

A general result in linear programming is that, on condition that the problem is bounded, the solution is always at the boundary of the feasible set and, more precisely, at a vertex of the polyhedron. Problem (20) may become unbounded if the polyhedral set is unbounded and there are feasible points such that the objective function can decrease indefinitely. We can summarize that, generally, due to the simple structure of (20), there are three possibilities:

1. The problem is not feasible, because the polyhedral set is empty.
2. The problem is unbounded.
3. The problem has a solution at a vertex of the polyhedral set.

From computational viewpoint, the polyhedral set has a finite number of vertices and an algorithm can be devised with the goal of finding a vertex solving the optimization problem in a finite number of steps. This is the basic idea behind the simplex method, which is an efficient numerical approach to solving linear programming problems. Besides the simplex algorithm, there are other, more contemporary methods, such as the interior point method.

Quadratic Programming

Besides linear programming, another class of problems with simple structure is the class of quadratic programming problems. It contains optimization problems with a quadratic objective function and linear equalities and inequalities in the constraint set:

$$\begin{aligned} \min_x \quad & c'x + \frac{1}{2}x'Hx \\ \text{subject to} \quad & Ax \leq b \end{aligned} \tag{21}$$

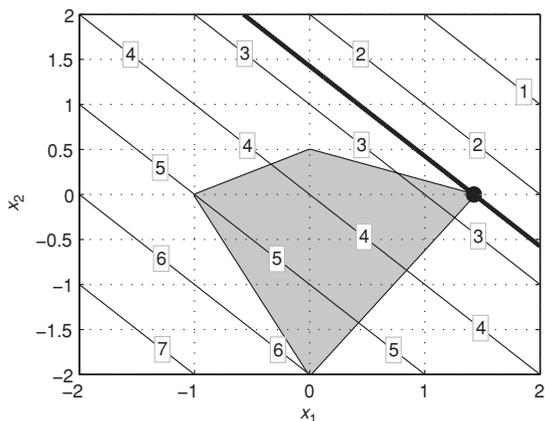

Figure 16 The Bottom Plot Shows the Tangential Contour Line to the Polyhedral Feasible Set

where

- $c = (c_1, \dots, c_n)$ is a vector of coefficients defining the linear part of the objective function
- $H = \{h_{ij}\}_{i,j=1}^n$ is an $n \times n$ matrix defining the quadratic part of the objective
- $A = \{a_{ij}\}$ is a $k \times n$ matrix defining k linear inequalities in the constraint set
- $b = (b_1, \dots, b_k)$ is a vector of real numbers defining the right-hand side of the linear inequalities

In optimal portfolio theory, mean-variance optimization problems in which portfolio variance is in the objective function are quadratic programming problems.

From the point of view of optimization theory, problem (21) is a convex optimization problem if the matrix defining the quadratic part of the objective function is positive semidefinite. In this case, the KKT conditions can be applied to solve it.

KEY POINTS

1. The mathematical theory of optimization concerns identifying the best alternative within a set of available, or feasible, alternatives and finds application in different areas of finance such as portfolio selection or, more generally, explaining behavior of economic agents in the face of uncertainty.
2. An optimization problem has two important components: an objective function defining the criterion to be optimized and a feasibility set described by means of equality or inequality constraints.
3. The properties of the objective function and the feasibility set are used to distinguish different classes of optimization problems with specific conditions for optimality and numerical solution methods. The most important classes include linear, quadratic, and convex programming problems.
4. In the theory of portfolio selection, the classical mean-variance analysis belongs to the class of quadratic optimization problems.
5. Employing more general reward and risk measures can result in a convex optimization problem but if scenarios for assets returns are available, the portfolio selection problem can be simplified to a linear programming problem in some cases. Optimization of performance ratios can be related to quasi-convex programs.

Abstract: Meeting the challenges of modern investment practice involves the design of novel forms of investment solutions, as opposed to investment products customized to meet investors' expectations. These new forms of investment solutions rely on the use of improved, more efficient performance-seeking portfolio and liability-hedging portfolio building blocks, as well as on the use of improved dynamic allocation strategies. Understanding the conceptual and technical challenges involved in the design of improved benchmarks for the performance-seeking portfolio is critical.

Management is justified as an industry by the capacity of adding value through the design of investment solutions that match investors' needs. For more than 50 years, the industry has in fact mostly focused on security selection decisions as a single source of added value.

This sole focus has somewhat distracted the industry from another key source of added value, namely portfolio construction and asset allocation decisions. In the face of recent crises, and given the intrinsic difficulty in delivering added value through security selection

decisions only, the relevance of the old paradigm has been questioned with heightened intensity, and a new paradigm is starting to emerge.

Academic research has provided very useful guidance with respect to how asset allocation and portfolio construction decisions should be analyzed so as to best improve investors' welfare. In a nutshell, the "fund separation theorems" that lie at the core of modern portfolio theory advocate a separate management of performance and risk control objectives. In the context of asset allocation decisions with consumption/liability objectives, it can be shown that the suitable expression of the fund separation theorem provides rational support for *liability-driven investment* (LDI) techniques that have recently been promoted by a number of investment banks and asset management firms. These solutions involve on the one hand the design of a customized *liability-hedging portfolio* (LHP), the sole purpose of which is to hedge away as effectively as possible the impact of unexpected changes in risk factors affecting liability values (most notably interest rate and inflation risks), and on the other hand the design of a *performance-seeking portfolio* (PSP), whose raison d'être is to provide investors with an optimal risk-return trade-off.

One of the implications of this LDI paradigm is that one should distinguish two different levels of asset allocation decisions: allocation decisions involved in the design of the performance-seeking or the liability-hedging portfolio (design of better building blocks, or BBBs), and asset allocation decisions involved in the optimal split between the PSP and the LHP (designed of advanced asset allocation decisions, or AAAs). We address the question of better building blocks in detail in this entry and provide some thoughts on integrating these building blocks in asset allocation. More specifically, we mainly focus here on how to construct efficient performance-seeking portfolios.

In this entry we provide an overview of the key conceptual challenges involved in asset al-

location and portfolio construction in designing the performance-seeking portfolio. We begin by presenting the fundamental principle of the maximization of risk/reward efficiency and then deal with estimation of risk parameters and expected return parameters. The empirical results of optimal portfolio construction modeling are presented. We also provide a brief discussion on integrating such properly designed building blocks in the overall PSP at the asset allocation level.

THE TANGENCY PORTFOLIO AS THE RATIONALE BEHIND SHARPE RATIO MAXIMIZATION

Modern portfolio theory provides some useful guidance with respect to the optimal design of a PSP that would best suit investors' needs. More precisely, the prescription is that the PSP should be obtained as the result of a portfolio optimization procedure aiming at generating the highest risk-reward ratio.

Portfolio optimization is a straightforward procedure, at least in principle. In a mean-variance setting, for example, the prescription consists of generating a maximum Sharpe ratio (MSR) portfolio based on expected return, volatility, and pairwise correlation parameters for all assets to be included in the portfolio, a procedure that can even be handled analytically in the absence of portfolio constraints.

More precisely, consider a simple mean-variance problem:

$$\max_w \mu_p - \frac{1}{2} \gamma \sigma_p^2$$

Here, the control variable is a vector w of optimal weight allocated to various risky assets, μ_p denotes the portfolio expected return, and σ_p denotes the portfolio volatility. We further assume that the investor is facing the following investment opportunity set: a riskless bond paying the risk-free rate r , and a set of N risky

assets with expected return vector μ (of size N) and covariance matrix Σ (of size $N \times N$), all assumed constant so far.

With these notations, the portfolio expected return and volatility are respectively given by:

$$\begin{aligned}\mu_p &= w'(\mu - re) + r \\ \sigma_p^2 &= w'\Sigma w\end{aligned}$$

In this context, it is straightforward to show by standard arguments that the only efficient portfolio composed with risky assets is the maximum Sharpe ratio portfolio, also known as the tangency portfolio.¹

Finally, the Sharpe ratio reads (where we further denote by e vector of ones of size N):

$$SR = \frac{w'(\mu - re)}{(w'\Sigma w)^{1/2}}$$

And the optimal portfolio is given by:

$$\begin{aligned}\max_w \left(\mu_p - \frac{1}{2}\gamma\sigma_p^2 \right) &\Rightarrow w_0^* = \frac{1}{\gamma}\Sigma^{-1}(\mu - re) \\ &= \frac{e'\Sigma^{-1}(\mu - re)}{\gamma} \underbrace{\frac{\Sigma^{-1}(\mu - re)}{e'\Sigma^{-1}(\mu - re)}}_{PSP}\end{aligned}\quad (1)$$

This is a two-fund separation theorem, which gives the allocation to the MSR performance-seeking portfolio (PSP), with the rest invested in cash, as well as the composition of the MSR performance-seeking portfolio.

In practice, investors end up holding more or less imperfect proxies for the truly optimal performance-seeking portfolio, if only because of the presence of parameter uncertainty, which makes it impossible to obtain a perfect estimate for the maximum Sharpe ratio portfolio. Denoting by λ the Sharpe ratio of the (generally inefficient) PSP actually held by the investor, and by σ its volatility, we obtain the following optimal allocation strategy:

$$w_0^* = \frac{\lambda}{\gamma\sigma}PSP \quad (2)$$

Hence the allocation to the performance-seeking portfolio is a function of two objective parameters, the PSP volatility and the PSP

Sharpe ratio, and one subjective parameter, the investor's risk aversion. The optimal allocation to the PSP is inversely proportional to the investor's risk aversion. If risk aversion goes to infinity, the investor holds the risk-free asset only, as should be expected. For finite risk-aversion levels, the allocation to the PSP is inversely proportional to the PSP volatility, and it is proportional to the PSP Sharpe ratio. As a result, if the Sharpe ratio of the PSP is increased, one can invest more in risky assets. Hence, portfolio construction modeling is not only about risk reduction; it is also about performance enhancement through a better spending of investors' risk budgets.

The expression (1) is useful because it provides in principle a straightforward expression for the optimal portfolio starting from a set of N risky assets. In the presence of a realistically large number N of securities, the curse of dimensionality, however, makes it practically impossible for investors to implement such direct one-step portfolio optimization decisions involving all individual components of the asset mix. The standard alternative approach widely adopted in investment practice consists instead in first grouping individual securities in various asset classes according to various dimensions, for example, country, sector, and/or style within the equity universe, or country, maturity, and credit rating within the bond universe, and subsequently generating the optimal portfolio through a two-stage process. On the one hand, investable proxies are generated for maximum Sharpe ratio (MSR) portfolios within each asset class in the investment universe. We call this step, which is typically delegated to professional money managers, the portfolio construction step. On the other hand, when the MSR proxies are obtained for each asset class, an optimal allocation to the various asset classes is eventually generated so as to generate the maximum Sharpe ratio at the global portfolio level. This step is called the asset allocation step, and it is typically handled by a centralized decision maker (e.g., a pension fund CIO) with or

without the help of specialized consultants, as opposed to being delegated to decentralized asset managers. In this entry, the discussion focuses on the first step, and we provide some concluding remarks on its relation to the second step at the end of this entry.

For the definition of *building blocks for asset allocation*, in the absence of active views, the default option consists of using market cap weighted indexes as proxies for the asset class MSR portfolio. Academic research, however, has found that such market cap indexes were likely to be severely inefficient portfolios.² In a nutshell, market cap weighted indexes are not good choices as investment benchmarks because they are poorly diversified portfolios. In fact, cap-weighting tends to lead to exceedingly high concentration in relatively few stocks. As a consequence of their lack of diversification, cap weighted indexes have been empirically found to be severely inefficient portfolios, which do not provide investors with the fair reward given the risk taken. As a result of their poor diversification, they have been found to be dominated by equally weighted benchmarks,³ which are naïvely diversified portfolios that are optimal if and only if all securities have identical expected return, volatilities, and all pairs of correlations are identical.

In what follows, we analyze in some detail a number of alternatives based on practical implementation of modern portfolio theory that have been suggested to generate more efficient proxies for the MSR portfolio in the equity investment universe. (See Figure 1.)

Modern portfolio theory was born with the efficient frontier analysis of Markowitz (1952). Unfortunately, early applications of the technique, based on naïve estimates of the input parameters, have been found of little use because they lead to nonsensible portfolio allocations.

In a first section, we explain how to help bridge the gap between portfolio theory and portfolio construction by showing how to generate enhanced parameter estimates so as to improve the quality of the portfolio optimiza-

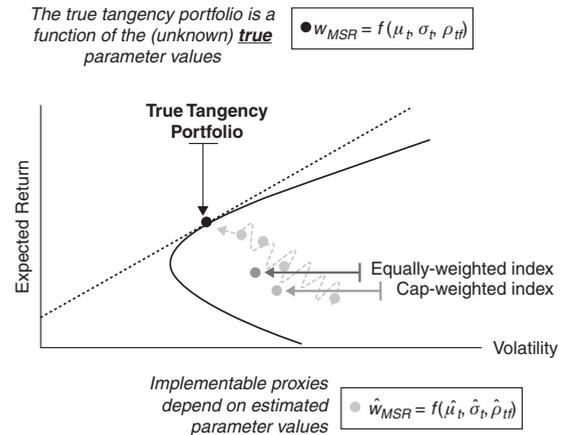

Figure 1 Inefficiency of Cap-Weighted Benchmarks, and the Quest for an Efficient Proxy for the True Tangency Portfolio

tion outputs (optimal portfolio weights). We first focus on enhanced covariance parameter estimates and explain how to meet the main challenge of sample risk reduction.⁴ Against this backdrop, we present the state-of-the-art methodologies for reducing the problem dimensionality and estimating the covariance matrix with multifactor models. We then turn to expected return estimation. We argue that statistical methodologies are not likely to generate any robust expected return estimates, which suggests that economic models such as the single-factor CAPM and the multifactor APT should instead be used for expected return estimation. Finally, we also present evidence that proxies for expected return estimates should not only include systematic risk measures, but they should also incorporate idiosyncratic risk measures as well as downside risk measures.

ROBUST ESTIMATORS FOR COVARIANCE PARAMETERS

In practice, success in the implementation of a theoretical model relies not only upon its conceptual grounds but also on the reliability of the inputs of the model. In the case of

mean-variance (MV) optimization the results will highly depend on the quality of the parameter estimates: the covariance matrix and the expected returns of assets.

Several improved estimates for the covariance matrix have been proposed, including most notably the factor-based approach suggested by Sharpe (1963), the constant correlation approach suggested by Elton and Gruber (1973), and the statistical shrinkage approach suggested by Ledoit and Wolf (2004). In addition, Jagannathan and Ma (2003) find that imposing (non-short selling) constraints on the weights in the optimization program improves the risk-adjusted out-of-sample performance in a manner that is similar to some of the aforementioned improved covariance matrix estimators.

In these papers, the authors have focused on testing the out-of-sample performance of global minimum variance (GMV) portfolios, as opposed to the MSR portfolios (also known as tangency portfolios), given that there is a consensus around the fact that purely statistical estimates of expected returns are not robust enough to be used. (This is discussed later in this entry.)

The key problem in covariance matrix estimation is the curse of dimensionality; when a large number of stocks are considered, the number of parameters to estimate grows exponentially, where the majority of them are pairwise correlations.

Therefore, at the estimation stage, the challenge is to reduce the number of factors that come into play. In general, a multifactor model decomposes the (excess) return (in excess to the risk-free asset) of an asset into its expected rewards for exposition to the “true” risk factors as follows:

$$r_{it} = \alpha_{it} + \sum_{j=1}^K \beta_{i,jt} \cdot F_{jt} + \varepsilon_{it}$$

or in matrix form for all N assets:

$$r_t = \alpha_t + \beta_t F_t + \varepsilon_t$$

where β_t is an $N \times K$ matrix containing the sensitivities of each asset i with respect to the corresponding j -th factor movements; r_t is the vector of the N assets' (excess) returns, F_t a vector containing the K risk factors' (excess) returns, and ε_t the $N \times 1$ vector containing the zero mean uncorrelated residuals ε_{it} . The covariance matrix for the asset returns implied by a factor model is given by:

$$\Omega = \beta \cdot \Sigma_F \cdot \beta^T + \Sigma_\varepsilon$$

where Σ_F is the $K \times K$ covariance matrix of the risk factors and Σ_ε an $N \times N$ covariance matrix of the residuals corresponding to each asset.

While the factor-based estimator is expected to allow for a reasonable trade-off between sample risk and model risk, there still remains, however, the problem of choosing the “right” factor model. One popular approach aims at relying as little as possible on strong theoretical assumptions by using principal components analysis (PCA) to determine the underlying risk factors from the data. The PCA method is based on a spectral decomposition of the sample covariance matrix, and its goal is to explain covariance structures using only a few linear combinations of the original stochastic variables, which will constitute the set of (unobservable) factors.

Bengtsson and Holst (2002) and Fujiwara et al. (2006) motivate the use of PCA in a similar way, extracting principal components in order to estimate expected correlation within MV portfolio optimization. Fujiwara et al. (2006) find that the realized risk-return of portfolios based on the PCA method outperforms the single-index-based one and that the optimization gives a practically reasonable asset allocation. Overall, the main strength of the PCA approach at this stage is that it allows “the data to talk” and has them tell the financial modeler what the underlying risk factors are that govern most of the variability of the assets at each point in time. This strongly contrasts with having to rely on the assumption that a particular factor model is the true pricing model and reduces the

specification risk embedded in the factor-based approach while keeping the sample risk reduction.

The question of determining the appropriate number of factors to structure the correlation matrix is critical for the risk estimation when using PCA as a factor model. Several options have been proposed to answer this question, some of them with more theoretical grounds than others.

As a final note, we need to recognize that the discussion is so far cast in a mean-variance setting, which can in principle only be rationalized for normally distributed asset returns. In the presence of non-normally distributed asset returns, optimal portfolio selection techniques require estimates for variance-covariance parameters, along with estimates for higher-order moments and comoments of the return distribution. This is a formidable challenge that severely exacerbates the dimensionality problem already present with mean-variance analysis. In a recent paper, Martellini and Ziemann (2010) extend the existing literature, which has mostly focused on the covariance matrix, by introducing improved estimators for the coskewness and cokurtosis parameters. On the one hand, they find that the use of these enhanced estimates generates a significant improvement in investors' welfare. On the other hand, they find that also that when the number of constituents in the portfolios is large (e.g., exceeding 20), the increase in sample risk related to the need to estimate higher-order comoments by far outweighs the benefits related to considering a more general portfolio optimization procedure. In the end, when portfolio optimization is performed on the basis of a large number of individual securities, it appears that maximizing the portfolio Sharpe ratio leads to a better out-of-sample return-to-VaR ratio or return-to-CVaR ratio compared to a procedure focusing on maximizing the return-to-VaR ratio or the return-to-CVaR ratio, a result that holds true even if improved estimators are used for higher-order comoments.

ROBUST ESTIMATORS FOR EXPECTED RETURNS

While it appears that risk parameters can be estimated with a fair degree of accuracy, it has been shown (Merton, 1980) that expected returns are difficult to obtain with a reasonable estimation error. What makes the problem worse is that optimization techniques are very sensitive to differences in expected returns, so that portfolio optimizers typically allocate the largest fraction of capital to the asset class for which estimation error in the expected returns is the largest.⁵

In the face of the difficulty of using sample-based expected return estimates in a portfolio optimization context, a reasonable alternative consists in using some risk estimate as a proxy for excess expected returns.⁶ This approach is based on the most basic principle in finance; that is, the natural relationship between risk and reward. In fact, standard asset pricing theories such as the arbitrage pricing theory as proposed by Ross (1976) imply that expected returns should be positively related to systematic volatility, such as measured through a factor model that summarizes individual stock return exposure with respect to a number of rewarded risk factors.

More recently, a series of papers have focused on the explanatory power of idiosyncratic, as opposed to systematic, risk for the cross section of expected returns. In particular, Malkiel and Xu (2006), extending an insight from Merton (1987), show that an inability to hold the market portfolio, whatever the cause, will force investors to care about total risk to some degree in addition to market risk so that firms with larger firm-specific variances require higher average returns to compensate investors for holding imperfectly diversified portfolios.⁷ That stocks with high idiosyncratic risk earn higher returns has also been confirmed in a number of recent empirical studies, including in particular Tinic and West (1986) as well as Malkiel and Xu (1997, 2006).

Taken together, these findings suggest that total risk, a model-free quantity given by the sum of systematic and specific risk, should be positively related to expected return. Most commonly, total risk is the volatility of a stock's returns. Martellini (2008) has investigated the portfolio implications of these findings and has found that tangency portfolios constructed on the assumption that the cross-section of excess expected returns could be approximated by the cross-section of volatility posted better out-of-sample risk-adjusted performance than their market-cap-weighted counterparts.

More generally, recent research suggests that the cross-section of expected returns might be best explained by risk indicators taking into account higher-order moments. Theoretical models have shown that, in exchange for higher skewness and lower kurtosis of returns, investors are willing to accept expected returns lower (and with volatility higher) than those of the mean-variance benchmark.⁸ More specifically, skewness and kurtosis in individual stock returns (as opposed to the skewness and kurtosis of aggregate portfolios) have been shown to matter in several papers. High skewness is associated with lower expected returns in Barberis and Huang (2004), Brunnermeier, Gollier, and Parker (2005), and Mitton and Vorkink (2007). The intuition behind this result is that investors like to hold positively skewed portfolios. The highest skewness is achieved by concentrating portfolios in a small number of stocks that themselves have positively skewed returns. Thus investors tend to be underdiversified and drive up the price of stocks with high positive skewness, which in turn reduces their future expected returns. Stocks with negative skewness are relatively unattractive and thus have low prices and high returns. The preference for kurtosis is in the sense that investors like low kurtosis and thus expected returns should be positively related to kurtosis. Boyer, Mitton, and Vorkink (2010) and Conrad, Dittmar and Ghysels (2008) provide empirical evidence that individual stocks' skewness and kurtosis is in-

deed related to future returns. An alternative to direct consideration of the higher moments of returns is to use a risk measure that aggregates the different dimensions of risk. In this line, Bali and Cakici (2004) show that future returns on stocks are positively related to their value-at-risk and Estrada (2000) and Chen, Chen, and Chen (2009) show that there is a relationship between downside risk and expected returns.

IMPLICATIONS FOR BENCHMARK PORTFOLIO CONSTRUCTION

Once careful estimates for risk and return parameters have been obtained, one may then design efficient proxies for an asset class benchmark with an attractive risk-return profile. For example, Amenc et al. (2011) find that efficient equity benchmarks designed on the basis of robust estimates for risk and expected return parameters substantially outperform in terms of risk-adjusted performance market cap weighted indexes that are often used as default options for investment benchmarks in spite of their well-documented lack of efficiency.⁹

Table 1, borrowed from Amenc et al. (2011), shows summary performance statistics for an efficient index constructed according to the aforementioned principles. For the average return, volatility, and the Sharpe ratio, we report differences with respect to cap-weighting and assess whether this difference is statistically significant.

Table 1 shows that the efficient weighting of index constituents leads to higher average returns, lower volatility, and a higher Sharpe ratio. All these differences are statistically significant at the 10% level, whereas the difference in Sharpe ratios is significant even at the 0.1% level. Given the data, it is highly unlikely that the unobservable true performance of efficient weighting was not different from that of capitalization weighting. Economically, the

Table 1 Risk and Return Characteristics for the Efficient Index

Index	Ann. Average Return (compounded)	Ann. Standard Deviation	Sharpe Ratio (compounded)	Information Ratio	Tracking Error
Efficient index	11.63%	14.65%	0.41	0.52	4.65%
Cap-weighted	9.23%	15.20%	0.24	0.00	0.00%
Difference (efficient minus cap-weighted)	2.40%	-0.55%	0.17	-	-
<i>p</i> -value for difference	0.14%	6.04%	0.04%	-	-

The table shows risk and return statistics portfolios constructed with the same set of constituents as the cap-weighted index. Rebalancing is quarterly subject to an optimal control of portfolio turnover (by setting the reoptimization threshold to 50%). Portfolios are constructed by maximizing the Sharpe ratio given an expected return estimate and a covariance estimate. The expected return estimate is set to the median total risk of stocks in the same decile when sorting by total risk. The covariance matrix is estimated using an implicit factor model for stock returns. Weight constraints are set so that each stock's weight is between $1/2N$ and $2/N$, where N is the number of index constituents. The *p*-values for differences are computed using the paired *t*-test for the average, the *F*-test for volatility, and a Jobson-Korkie test for the Sharpe ratio. The results are based on weekly return data from 01/1959 to 12/2008.

performance difference is pronounced, as the Sharpe ratio increases by about 70%.

ASSET ALLOCATION MODELING: PUTTING THE EFFICIENT BUILDING BLOCKS TOGETHER

After efficient benchmarks have been designed for various asset classes, these building blocks can be assembled in a second step, the asset allocation step, to build a well-designed multiclass performance-seeking portfolio.

While the methods we have discussed so far can in principle be applied in both contexts, a number of key differences should be emphasized.

In the asset allocation context, the number of constituents is small, and using time- and state-dependent covariance matrix estimates becomes reasonable, while they do not necessarily improve the situation in portfolio construction contexts when the number of constituents is large. Similarly, while it is not feasible in general, as explained above, to perform portfolio optimization with higher-order moments in a portfolio construction context where the number of constituents is typically

large, it is reasonable to go beyond mean-variance analysis in an asset allocation context where the number of constituents is limited.

Furthermore, in an asset allocation context, the universe is not homogenous, which has implications for expected returns and covariance estimation. In terms of a covariance matrix, it will not prove easy to obtain a universal factor model for the whole investment universe. In this context, it is arguably better to use statistical shrinkage toward, say, the constant correlation model, as opposed to using a factor model approach.¹⁰

KEY POINTS

- Modern portfolio theory advocates the separation of the management of performance and risk control objectives. In the context of asset allocation decisions, the fund separation theorem provides rational support for liability-driven investment techniques whose solutions involve the design of a customized liability-hedging portfolio and the design of a performance-seeking portfolio.
- The sole purpose of the liability-hedging portfolio is to hedge away as effectively as possible the impact of unexpected changes in risk

factors affecting liability values (most notably interest rate and inflation risks); the purpose of the performance-seeking portfolio is to provide investors with an optimal risk-return trade-off.

- An implication of the liability-driven investment paradigm is that one should distinguish two different levels of asset allocation decisions: (1) decisions involved in the design of the performance-seeking or the liability-hedging portfolio (design of better building blocks), and (2) decisions involved in the optimal split between the performance-seeking portfolio and liability-hedging portfolio (designed of advanced asset allocation decisions).
- Although modern portfolio theory provides some useful guidance with respect to the optimal design of performance-seeking portfolios that would best suit investors' needs, in practice, investors end up holding more or less imperfect proxies for the truly optimal performance-seeking portfolio, if only because of the presence of parameter uncertainty, which makes it impossible to obtain a perfect estimate for the maximum Sharpe ratio portfolio.
- The allocation to the performance-seeking portfolio is a function of two objective parameters, the PSP volatility and the PSP Sharpe ratio, and one subjective parameter, the investor's risk aversion. The optimal allocation to the PSP is inversely proportional to the investor's risk aversion.
- In practice, the success in the implementation of a theoretical model relies not only upon its conceptual grounds but also on the reliability of the inputs of the model. In the case of mean-variance optimization the results will highly depend on the quality of the parameter estimates: the covariance matrix and the expected returns of assets.
- Several improved estimates for the covariance matrix have been proposed: the factor-based approach, constant correlation approach, and statistical shrinkage approach.
- The key problem in covariance matrix estimation is the curse of dimensionality. Consequently, at the estimation stage, the challenge is to reduce the number of factors that come into play. In general, a multifactor model decomposes the (excess) return (in excess to the risk-free asset) of an asset into its expected rewards for exposition to the "true" risk factors.
- The problem of choosing the right factor model still remains. The statistical technique of principal components analysis is commonly used to determine the underlying risk factors from the data.
- While it appears that risk parameters can be estimated with a fair degree of accuracy, it has been shown that expected returns are difficult to obtain with a reasonable estimation error. What makes the problem worse is that optimization techniques are very sensitive to differences in expected returns, so that portfolio optimizers typically allocate the largest fraction of capital to the asset class for which estimation error in the expected returns is the largest. In the face of the difficulty of using sample-based expected return estimates in a portfolio optimization context, a reasonable alternative consists in using some risk estimate as a proxy for excess expected returns.
- Research suggests that the cross-section of expected returns might be best explained by risk indicators taking into account higher-order moments. Theoretical models have shown that, in exchange for higher skewness and lower kurtosis of returns, investors are willing to accept expected returns lower (and volatility higher) than those of the mean-variance benchmark.
- Once careful estimates for risk and return parameters have been obtained, one may then design efficient proxies for an asset class benchmark with an attractive risk-return profile. After efficient benchmarks have been designed for various asset classes, these building blocks can be assembled in a second step, the asset allocation step, to build

a well-designed multiclass performance-seeking portfolio.

Asset Pricing Models

General Principles of Asset Pricing

GUOFU ZHOU, PhD

Frederick Bierman and James E. Spears Professor of Finance, Olin Business School,

Abstract: Asset pricing is mainly about transforming asset payoffs into prices. The most important principles of valuation are no-arbitrage, law of one price, and linear positive state pricing. These principles imply asset prices are linearly related to their discounted payoffs in which the stochastic discount factor is a function of investors' risk tolerance and economy-wide risks. The arbitrage pricing theory, the capital asset pricing model, and the consumption asset pricing model, among others, are special cases of the discount factor models.

In this entry, we discuss the general principles of asset pricing. Our focus here is to analyze asset pricing in a more general setup. Due to its generality, this entry is inevitably more abstract and challenging, but important for understanding the foundations of modern asset pricing theory. First, by extending the state-dependent contingent claims with two possible states allowing for an arbitrary number of states, we introduce the economic notions of complete market, the law of one price, and arbitrage. Then, we provide the fundamental theorem of asset pricing that ties these concepts to asset pricing relations. Subsequently, we discuss stochastic discount factor models, which is the unified framework of various asset pricing theories that include the *capital asset pricing model* (CAPM) (see Sharpe, 1964; Lintner, 1965; Mossin, 1966) and *arbitrage pricing theory* (APT) (see Ross, 1976) as special cases.

ONE-PERIOD FINITE STATE ECONOMY

If a security has payoffs, denoted by x ,

$$\tilde{x} = \begin{cases} \$1, & \text{up} \\ 0, & \text{down} \end{cases}$$

it means that the economy will have two states next period, up or down, and the security will have a value of \$1 or 0 in the up and down states, respectively. Similarly, as a simple extension, we can think that the economy has three states next period: good, normal, and bad. Then, any security in this economy must have three payoffs corresponding to the three states. For example,

$$\tilde{x} = \begin{cases} \$3, & \text{good} \\ \$2, & \text{normal} \\ \$1, & \text{bad} \end{cases}$$

is a security in the states economy with values of \$3, \$2, and \$1, respectively, in the three states. For notational brevity, we sometimes use the transposed vector dropping the dollar sign, $(3, 2, 1)'$, to denote the payoff of this security, where the apostrophe (') is the symbol for transpose.

In general, we can consider an economy with an arbitrary number of s states and N securities. In this economy, the payoff of any security can be expressed as

$$\tilde{x} = \begin{cases} v_1, & \text{State 1} \\ v_2, & \text{State 2} \\ \vdots & \vdots \\ v_s, & \text{State } s \end{cases} \quad (1)$$

where the v 's are the values of the security in the m states. For example, suppose state $s = 4$, then a security with payoff $(1.10, 1.10, 1.10, 1.10)'$ is a well-defined security in our four-state economy. Suppose further that the price of this security is \$1, then this security earns \$0.10 or 10% ($\$0.1/\1) regardless of the state. Hence, this security is risk free with a rate of return of 10% regardless of the state of the economy.

Suppose now that there is a total of N securities, $\tilde{x}_1, \dots, \tilde{x}_N$, in an economy of s states. We can summarize the payoffs next period of all the N securities by using the following matrix,

$$X = \begin{pmatrix} v_{11} & \dots & v_{1N} \\ \vdots & \ddots & \vdots \\ v_{s1} & \dots & v_{sN} \end{pmatrix} \quad (2)$$

where each of the N columns represents the values of the securities. It is evident that matrix X summarizes payoffs of all the securities and determines their future values completely.

The asset pricing question is how to determine the price for each of the securities. Mathematically, the pricing mechanism can be viewed as a mapping from the j -th security (or the s vector, the payoff obtained from owning the security), to a price p that an investor is willing to pay today,

$$\rho(\tilde{x}_j) = p_j \quad (3)$$

As it turns out, simple economic principles imply many useful properties for the mapping, which comprises the *general principles of asset pricing* to be discussed below.

PORTFOLIOS AND MARKET COMPLETENESS

In evaluating securities, a key principle is to evaluate them as a whole, and not in isolation. To do so, consider a portfolio of the N securities

$$\tilde{x}_p = \varphi_1 \tilde{x}_1 + \varphi_2 \tilde{x}_2 + \dots + \varphi_N \tilde{x}_N \quad (4)$$

where the φ 's are portfolio weights that now represent the units of the securities we purchase in the portfolio, and \tilde{x}_p is the payoff of the portfolio, which simply adds up the individual values. Note that the weights can be either positive or negative. A negative weight on a security is a short position. In the case where no short sales are allowed, the weights are restricted to be positive.

Note that the portfolio weights are often the percentages of money we invest in the securities, where prices are given and we are interested in the return on a portfolio. In contrast, we focus here on the weights in terms of units because we are interested in determining the prices from payoffs. However, once the prices are given, the weights in terms of either units or percentages are equivalent. To see this, if we express a portfolio in term of returns, denoted by R , rather than payoffs as above, then the portfolio return is

$$R_p = w_1 R_1 + w_2 R_2 + \dots + w_N R_N \quad (5)$$

where

$$R_j = \frac{\tilde{x}_j}{p_j}$$

is the gross return on security j , which is one plus the usual percentage return. The relation between the φ 's and the w 's is

$$w_j = \frac{\varphi_j p_j}{\varphi_1 p_1 + \dots + \varphi_N p_N} \quad (6)$$

where the numerator is the amount of money allocated to security j , and the denominator is the total amount of money invested in the securities, so that the w 's are the percentage weights as before.

Consider the following two securities in a two-state economy:

$$\tilde{x}_1 = \begin{cases} 1, & \text{up} \\ 0, & \text{down} \end{cases}, \quad \tilde{x}_2 = \begin{cases} 0, & \text{up} \\ 1, & \text{down} \end{cases}$$

Suppose their prices today are \$1. Then, with an investment of \$1 that buys 0.5 unit each of the securities, one obtains a portfolio

$$\tilde{x} = \varphi_1 \tilde{x}_1 + \varphi_2 \tilde{x}_2 = 0.5\tilde{x}_1 + 0.5\tilde{x}_2$$

with payoff

$$\tilde{x} = \begin{cases} 0.5, & \text{up} \\ 0.5, & \text{down} \end{cases}$$

One can also buy 2 units of the first security, and short one unit of the second security; then the resulting portfolio is

$$\tilde{x} = 2\tilde{x}_1 + (-1)\tilde{x}_2$$

with payoff

$$\tilde{x} = \begin{cases} 2, & \text{up} \\ -1, & \text{down} \end{cases}$$

Note that the payoff of the portfolio is negative, $-\$1$, in the down state. This means that when the economy is down, one has to buy back the second security at a price of \$1 (its value in the down state) to cover the short position. The net cost is \$1, the payoff of the portfolio in the down state. In contrast to the portfolio where equal dollar amounts are invested in both securities, this portfolio with short sales permitted has a higher payoff of \$2 in the up state, which compensates for the loss in the down state.

Redundant Assets

A portfolio is uniquely determined by its portfolio weights, which can be summarized by the N -vector

$$\varphi = (\varphi_1, \varphi_2, \dots, \varphi_N)'$$

The portfolio's payoffs are then uniquely determined by the s -vector,

$$\text{Payoff} = X\varphi \quad (7)$$

For example, one can easily verify that this is true in our first illustration in which X is simply equal to the identity matrix.

A portfolio φ is said to be replicable if we can find another portfolio with different weights, ω , such that their payoffs are equal

$$X\omega = X\varphi, \quad \omega \neq \varphi \quad (8)$$

In particular, if one of the x 's can be replicated by a portfolio of others, it is called a *redundant asset* or *redundant security*. In any economy, redundant securities can be eliminated without affecting the properties of all the possible portfolios of the remaining assets. Sometimes, in order to distinguish the securities, the x 's that define the economy, and all their possible portfolios, we will refer to the x 's as *primitive securities* because all other portfolios are composed of them.

Consider the following two-state economy

$$\tilde{x}_1 = \begin{cases} 1, & \text{up} \\ 0, & \text{down} \end{cases}, \quad \tilde{x}_2 = \begin{cases} 2, & \text{up} \\ 0, & \text{down} \end{cases}$$

with prices for both securities being \$1 and \$2 today. The portfolio with weight vector $\varphi = (0.5, 0.5)'$ is

$$\tilde{x} = 0.5\tilde{x}_1 + 0.5\tilde{x}_2$$

This portfolio is replicable because it is also equal to

$$\tilde{x} = 1.5\tilde{x}_1$$

The primitive asset x_2 is redundant here because its payoff is simply double the payoff of the first asset.

Complete Market

In an economy with N risky securities and s states, a security market is formed if arbitrary buying and shorting are allowed, which creates infinitely many possible portfolios. We say the

market is *complete* and is hence referred to as a *complete market*, if, for any possible payoff, there is a portfolio of the primitive securities to replicate it. That is, for any desired payoff \tilde{x} , we can find portfolio weights such that

$$\varphi_1 \tilde{x}_1 + \varphi_2 \tilde{x}_2 + \cdots + \varphi_N \tilde{x}_N = \tilde{x} \quad (9)$$

A complete market not only allows investors to obtain any desired payoff in any state (with a price), but also permits unique security pricing, as will be clear later.

For example, the two securities in our first example will form a complete market. This is because for any possible payoff

$$\tilde{x} = \begin{cases} a, & \text{up} \\ b, & \text{down} \end{cases}$$

the portfolio

$$a \tilde{x}_1 + b \tilde{x}_2$$

yields the payoff. To see why, if one investor wants to get a \$2 payoff in the up state and \$3 in the down state, buying 2 units of the first security and 3 units of the second security will provide what is exactly desired. However, the two securities in our second example above form an incomplete market. This is because for any possible portfolios consisting of the two securities, it will be impossible to create a payoff of \$1 in the down state.

In terms of matrix and vector notation, a complete market requires that, for any payoff vector, we can find portfolio weights φ to solve the linear equation with φ as the unknown variable

$$X\varphi = y \quad (10)$$

Note that X is an s by N matrix and y is an s -vector. Recall from linear algebra that the number of independent columns of X is called the *rank* of the matrix X , denoted as $\text{rank}(X)$ below. If $\text{rank}(X) = s$, the linear combinations of these columns will generate all possible s -vectors. That is, a portfolio of those securities whose payoffs are those independent columns is capable of producing any possible payoffs, or the market must be complete. Conversely,

if the above linear equation has a solution to any y , it must do so for s independent y 's, say, the s columns of the s -dimensional identity matrix, which is an s by s matrix with diagonal elements 1 and zero elsewhere. For example, if $s = 2$, the y 's correspond to the payoffs of the two securities in our first example. This means that the linear combinations of the columns of X are capable of yielding s independent columns. So, the number of independent columns must be greater than or equal to s . Since X is an s by N matrix, its number of independent columns, $\text{rank}(X)$, cannot be greater than s . Then the only possibility is equal to s .

We can summarize our discussion in the following proposition:

Market Completeness Proposition: The market is complete if and only if the rank of the s by N payoff matrix X is s , that is,

$$\text{rank}(X) = s \quad (11)$$

Consequently, for s possible states, we should have at least $N \geq s$ primitive assets for the market to be complete. One can verify that the rank condition holds for the two securities in our first example, but not in our second example.

THE LAW OF ONE PRICE AND LINEAR PRICING

In this section, we first discuss the law of one price and its relation to the linear pricing rule, and then introduce the concept of state price and relate it to the law of one price.

Linear Pricing

The *law of one price* (LOP) says that two assets with identical payoffs must have the same price. In international trade, in the absence of tariffs and transportation costs, an apple sold in New York City must have the same price as an apple sold in London after converting the money into the same currency. This provides an economic

channel through which to tie the currencies together. In the financial markets, the LOP says that we should not be able to profit from buying the same security at a higher price and selling it at a lower one.

Mathematically, under LOP, if two portfolios have the same payoffs

$$X\varphi = X\omega \quad (12)$$

then their prices today must be the same

$$\rho(X\varphi) = \rho(X\omega) \quad (13)$$

where, as we recall from our earlier discussion, ρ is the mapping that maps the payoff of an asset or of a portfolio into its price.

A simple necessary and sufficient condition for the LOP to hold is that every portfolio with zero payoff must have zero price. To see the necessity, suppose that there is an asset with zero payoff that sells at a nonzero price, say, \$0.01. We can combine this asset with any other asset to form a new asset without changing the payoff, but the price of this new asset is \$0.01 higher than before packaging the two assets. The LOP says that the old one and the new one must have the same price, which is, of course, a contradiction. Conversely, if two portfolios with an identical price were sold at different prices, say \$2.01 and \$2, buying the one with the price of \$2.01 and shorting the one with a price of \$2 creates an asset with zero payoff, but a price of \$0.01. This is not possible from the zero price condition.

The LOP essentially prevents an asset from having multiple prices, which gives rise to its name. Only when it is true is it possible for there to be rational pricing with a unique price. An important theoretical implication of the LOP is that the price mapping, the ρ function, must be linear:

$$\rho[X(a\varphi + b\omega)] = a\rho(X\varphi) + b\rho(X\omega) \quad (14)$$

That is, the price of a portfolio must be equal to a portfolio of the component prices. Intuitively, the price of two burgers must be two times the price of one, and the price of a burger

and a Coke must be the same as the sum of the two individual prices. The linear pricing rule is fundamental in finance. It implies that, if the share price of a company is its future cash flows, then no matter how one slices the cash flows, the price will remain unchanged and is equal to the values of the slices added together.

The linear pricing rule clearly implies the LOP. The price mapping is uniquely determined by the payoffs only, and so it must be the case that the prices are identical if the payoffs are. Conversely, if the LOP is true, paying the price of the left-hand side of equation (14) will result in a portfolio with the identical payoff as the right-hand side, and hence their prices must be the same. A formal statement of this is as follows:

Linear Pricing Rule: The law of one price is valid if and only if the linear pricing rule is true.

State Price

In asset pricing, the concept of a state price is fundamental. In our states economy, there are s states. The *state price* in state i is the price investors are willing to pay today to obtain one unit of payoff in that state, and nothing in other states. The state price is also known as the *Arrow-Debreu price*, named in honor of the originators. A *state price vector* will then be an s -vector of all the prices in all the states. If there exists a state price vector $q = (q_1, q_2, \dots, q_s)$, then we can write the asset price for each primitive security as

$$p_j = q_1 v_{1j} + q_2 v_{2j} + \dots + q_s v_{sj} \quad (15)$$

In words, this equation says that the price of the j -th security is equal to its payoffs in each of the states times the price per unit value in that state.

The state price is not only useful for linking the payoffs of the primitive securities to their prices, but also useful to price any new assets, including any other contingent claims or derivatives in the economy. All we need to do is

to identify the payoffs of these assets and then sum the products of the payoffs with their state prices to obtain asset prices.

The question is whether the state price vector always exists. We rewrite the state pricing relation (15) in matrix form as

$$p = X'q \quad (16)$$

The existence of the state price vector q is the existence of solution q to the linear equation given by (16). In our states economy here, we can show that the LOP is necessary and sufficient for the existence of the state price, while in more complex economies, say those with an infinite number of assets and an infinite number of states, some auxiliary condition may be needed.

Existence of State Price Condition: The law of one price is valid if and only if the state price vector exists.

The proof of the above follows from linear algebra. If the state price vector exists, then

$$p'\varphi = q X'\varphi = q X'\omega = p'\omega$$

which says that the price of the portfolio with weights φ is the same as the price of another portfolio as long as their payoffs are identical. Conversely, if the LOP is true, then for any portfolio weights w with zero payoff or satisfying $X'\varphi = 0$, we must have zero price or $p'\varphi = 0$. This means that p is orthogonal to every vector that is orthogonal to X . Now projecting p on the entire N -dimensional space, p must then be a linear combination of the columns of X . The combination coefficients are exactly equal to q , which is what we are looking for. The proof is therefore complete.

As an example, consider the following two securities in a two-state economy,

$$\tilde{x}_1 = \begin{Bmatrix} 1, & up \\ 0, & down \end{Bmatrix}, \quad \tilde{x}_2 = \begin{Bmatrix} 2, & up \\ 0, & down \end{Bmatrix}$$

where the first security has a price of \$1 and the second of \$2. Clearly the prices are consistent with the LOP. In this case, a state price of $(1, 0)'$

can price all portfolios of the two securities:

$$1 = 1 \times 1 + 0 \times 0$$

and

$$2 = 1 \times 2 + 0 \times 0$$

Another state price $(1, 2)'$ can also do the same. A more subtle case is in an economy when

$$\tilde{x}_1 = \begin{Bmatrix} 1, & up \\ 1, & down \end{Bmatrix}, \quad \tilde{x}_2 = \begin{Bmatrix} 2, & up \\ 2, & down \end{Bmatrix}$$

with the same prices of \$1 and \$2. Then $(0.5, 0.5)'$ and $(0.2, 0.8)'$ both, among others, price the two primitive securities and all their portfolios correctly.

Under what conditions will the state price be unique? To find the conditions, recall the matrix form of the state pricing relation

$$p = X'q$$

The LOP is equivalent to the existence of the state price vector q . If the market is in addition complete, then q in the above equation can be uniquely solved as

$$q = (XX')^{-1}Xp \quad (17)$$

Note that X is s by N , so its inverse is undefined unless $s = N$. But the inverse of the s by s matrix, XX' , is well defined. Equation (17) leads to our next proposition.

Uniqueness of State Price Proposition: If the law of one price holds, and if the market is complete, the state price must exist and be unique.

For example, consider the following two securities in a two-state economy

$$\tilde{x}_1 = \begin{Bmatrix} 1, & up \\ 2, & down \end{Bmatrix}, \quad \tilde{x}_2 = \begin{Bmatrix} 3, & up \\ 4, & down \end{Bmatrix}$$

where the first security has a price of \$4 and the second of \$10. We can check that both the rank and LOP conditions are true. The unique state price vector is then given by equation (17),

$$\begin{bmatrix} q_1 \\ q_2 \end{bmatrix} = \begin{pmatrix} 5 & -3.5 \\ -3.5 & 2.5 \end{pmatrix} \begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix} \begin{bmatrix} 4 \\ 10 \end{bmatrix} = \begin{bmatrix} 2 \\ 1 \end{bmatrix}$$

It can be verified that these prices indeed work for pricing the two primitive securities.

ARBITRAGE AND POSITIVE STATE PRICING

The assumption of the absence of arbitrage is the foundation upon which asset pricing theories rely. When there are any free lunches or what economists refer to as *arbitrage opportunities*, asset prices are not rational. Investors are likely to be able to correct the prices by exploiting the arbitrage opportunities, and eventually these opportunities will disappear, and the prices will reflect their true values. Asset pricing theory is largely concerned with these equilibrium true values.

In our states economy, the concept of arbitrage can be formally defined. There are two types of arbitrage. The first type exists if there is a portfolio strategy that requires no investment today (i.e., referred to earlier as a zero-investment strategy) and yet yields nonnegative payoffs in the future, and positive (or not identical to zero) at least in one of the states. Mathematically, this type of arbitrage can be expressed as

$$X\varphi \geq 0, \text{ and not equal to zero}$$

with

$$p_1\varphi_1 + p_2\varphi_2 + \cdots + p_N\varphi_N \leq 0$$

The second type of arbitrage is one in which a portfolio strategy earns money today, and yet has no future obligations. We can express this mathematically as follows:

$$X\varphi \geq 0$$

with

$$p_1\varphi_1 + p_2\varphi_2 + \cdots + p_N\varphi_N < 0$$

Consider as an example the following two securities in a two-state economy:

$$\tilde{x}_1 = \begin{cases} 1, & \text{up} \\ 2, & \text{down} \end{cases}, \quad \tilde{x}_2 = \begin{cases} 2, & \text{up} \\ 4.1, & \text{down} \end{cases}$$

with prices \$1 and \$2. If we follow a strategy that involves shorting two units of the first security and buying one unit of the second security, then our net investment will be zero, but the payoffs will be

$$-2 \times \tilde{x}_1 + 1 \times \tilde{x}_2 = \begin{bmatrix} 0 \\ 0.1 \end{bmatrix}$$

This is an arbitrage of the first type. However, there is no arbitrage of the second type. This is because for any weights φ_1 and φ_2 , if the cost is negative, that is,

$$\varphi_1 + 2\varphi_2 < 0$$

then the payoff in the up state of the portfolio,

$$\varphi_1 + 2\varphi_2$$

will be negative too.

To illustrate, consider the following two securities in a two-state economy,

$$\tilde{x}_1 = \begin{cases} 1, & \text{up} \\ -1, & \text{down} \end{cases}, \quad \tilde{x}_2 = \begin{cases} 2, & \text{up} \\ -4, & \text{down} \end{cases}$$

with prices \$1 and \$1.9. If we short two units of the first security and buy one unit of the second security, then our net investment will be

$$(-2) \times 1 + 1 \times 1.9 = -0.1$$

but the payoffs will be

$$-2 \times \tilde{x}_1 + 1 \times \tilde{x}_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

This is an arbitrage of the second type. However, there is no arbitrage of the first type. This is because for any weights φ_1 and φ_2 , the arbitrage requires the portfolio payoffs be nonnegative

$$\varphi_1 + 2\varphi_2 \geq 0$$

and

$$-\varphi_1 - 2\varphi_2 \geq 0$$

in the two states, respectively. The only non-negative payoffs for both the states is the zero payoff in this case. So, there cannot be an arbitrage of the first type.

Note that the pricing operator is to map the payoffs of an asset to its price, and it provides

that the state price of the payoff is \$1 in that state and nothing in other states. If the state price in one state is zero, this will be clearly an arbitrage opportunity as an investor can get future payoffs in this state for paying a zero price today. To rule out arbitrage opportunities in the economy, it is hence necessary to require the state prices be positive. When the pricing operator is both linear and implying positive state prices, we call it a positive linear pricing rule. As it turns out below, the existence of such a positive linear pricing rule is equivalent to the absence of arbitrage opportunities in the economy.

Arbitrage is also related to the LOP. If there is no arbitrage, the LOP must be true. This is because if two portfolios with two identical payoffs were sold at different prices, a “buy low and sell high” strategy will result in the construction of a portfolio with zero payoffs in the future, but with positive proceeds today. This is an arbitrage of the first type. Thus, the no-arbitrage condition is stronger than the LOP. In finance, the assumption of no arbitrage is crucial, as explained next by the fundamental theorem of asset pricing.

THE FUNDAMENTAL THEOREM OF ASSET PRICING

Consider now an investor’s utility maximization problem. Assume the investor prefers more to less, so that the utility function is monotonic in the consumption level. Given an initial wealth W_0 , and given the trading opportunities, the investor’s future consumption, as a vector in the s states, will be

$$C_1 = W_1 + (W_0 - C_0) \times R_p$$

where

C_0 = consumption (measured in dollars) today,

R_p = return on a portfolio of assets, which can be optimally chosen by the investor maximizing his or her utility, and
 W_1 = the investor’s income from other sources next period, such as labor income

The utility is a monotonic function of both C_0 and C_1 .

Then the following theorem ties together the no-arbitrage, positive linear pricing rule, and the utility maximization problem.

Fundamental Theorem of Asset Pricing: The following are equivalent:

1. Absence of arbitrage
2. Existence of a positive linear pricing rule
3. Existence of an investor with monotonic preference whose utility is maximized

We provide a simplified proof here. (A more rigorous proof is provided in Dybvig and Ross (1987).)

To see that the absence of arbitrage implies existence of a positive linear pricing rule, we note first that earlier we provided the argument for the existence of the linear pricing rule. The positivity of the state prices must be true in the absence of arbitrage. This is because, if there is a zero or negative state price in some state, then the payoffs in this state are free lunches, so arbitrage opportunities can arise. Conversely, if the state prices are positive, every single payoff in each state has a positive price, and there cannot be any free lunch.

Mathematically, this can also be easily demonstrated. If φ is an arbitrage portfolio so that its price is zero or negative, then

$$0 \geq p'\varphi = (X'q)'\varphi = q'(X\varphi)$$

where the first equality is the linear pricing rule, and the second equality holds by matrix multiplication rules. Because of positive state prices, all components of q are positive. If $p'\varphi$ is zero, $X\varphi$ must be all zeros, and if $p'\varphi$ is negative, $X\varphi$ must have strictly negative components. Both contradict the assumption that φ is an arbitrage portfolio. Hence, there are no arbitrage opportunities when the state prices are positive.

To see how the existence of a positive linear pricing rule implies the existence of an investor with monotonic preference whose utility is maximized, the consumption of the investor in each state must be finite since the investor has finite wealth, and since the investor faces a binding budget constraint due to positive state prices. Finally, the existence of an investor with monotonic preference whose utility is maximized clearly implies the absence of arbitrage. This is because adding an arbitrage portfolio (i.e., a free lunch) to the investor's portfolio will only strictly increase his or her utility without affecting the budget, contradicting the fact that the utility is maximized to begin with. This concludes our proof.

An important insight from the fundamental theorem is what we need for rational pricing. In deriving pricing formulas, many theoretical equilibrium asset pricing models assume all investors behave rationally and have identical information sets. The theorem says that, to rationally price assets or to ensure market pricing efficiency, we do not need to assume that all investors are smart. What we need is a few smart ones who can capitalize on any arbitrage opportunities. Then, the prices should be in line with their payoffs in the economy.

The Discount Factor

Related to the fundamental theorem is the concept of the discount factor. As it turns out, this is the common feature of almost all asset pricing models, a point that will become evident in the next section. Let $\theta_i > 0$ be the probability for state i to occur. The linear pricing rule given by equation (15) can be rewritten as

$$p_j = \theta_1(q_1/\theta_1)v_{1j} + \theta_2(q_2/\theta_2)v_{2j} + \cdots + \theta_s(q_s/\theta_s)v_{sj} = E(mv_j) \quad (18)$$

where m is a random variable whose value in state s is equal to

$$m_s = \frac{q_i}{\theta_s} \quad (19)$$

Equation (18) says that the price for asset j is given by the expected value of its payoff multiplied by a random variable m , where m is common for all assets.

Suppose now that there is a risk-free asset in the economy that can earn a risk-free interest rate r , and that the price of this risk-free asset today is \$1 (we can scale the asset unit if necessary). Then the payoff of this risk-free asset's price in the next period will be $1 + r$ in all the states. So, by equation (18), we have for the following expected payoff for this risk-free asset

$$1 = E[m(1 + r)]$$

and therefore

$$E[m] = \frac{1}{1 + r} \quad (20)$$

If there were no risks in the economy, and if there were no arbitrage, it is clear that all assets should earn the same risk-free rate of return. Hence, assets should be priced by their present values of the cash flows, or the prices are equal to the discounted cash flows with the discount factor $1/(1 + r)$. When there is risk as is the case now, the payoffs are multiplied by the random variable m whose mean is $1/(1 + r)$. This is why m is also known as a stochastic discount factor because (1) it is random, and (2) it extends the risk-free discounting to the risky asset case.

Consider, for example, three securities in a three-state economy with prices \$5, \$5, and \$6, and with the following payoff matrix:

$$X = \begin{pmatrix} 10 & 20 & 30 \\ 10 & 10 & 10 \\ 10 & 5 & 5 \end{pmatrix}$$

In this economy, the first asset is the risk-free asset since it has a constant payoff of \$10 regardless of the future state. Moreover, the risk-free rate is 100% because the asset is sold at a price of \$5. The state price vector can be solved using equation (17) and is $q = (0.1, 0.2, 0.2)'$. Assume the probability for each state is $1/3$. Then the

linear pricing rule can be expressed as

$$\begin{aligned} 5 = p_1 &= \frac{1}{3} \times (0.3 \times 10) + \frac{1}{3} \times (0.6 \times 10) \\ &\quad + \frac{1}{3} \times (0.6 \times 10), \\ 5 = p_2 &= \frac{1}{3} \times (0.3 \times 20) + \frac{1}{3} \times (0.6 \times 10) \\ &\quad + \frac{1}{3} \times (0.6 \times 5), \\ 6 = p_3 &= \frac{1}{3} \times (0.3 \times 30) + \frac{1}{3} \times (0.6 \times 10) \\ &\quad + \frac{1}{3} \times (0.6 \times 5) \end{aligned}$$

Let m be a random variable that has values 0.3, 0.6, and 0.6 in the three possible states. Then the above says that, for each asset, the price is the expected value of the discounted payoff. The mean of the discount factor is

$$\begin{aligned} E[m] &= \frac{1}{3} \times 0.3 + \frac{1}{3} \times 0.6 + \frac{1}{3} \times 0.6 = 0.5 \\ &= \frac{1}{1 + 100\%} \end{aligned}$$

This verifies equation (19).

The state price vector, or equivalently the discount factor, is not only useful for pricing primitive assets, but also useful to price any portfolio consisting of them, as well as derivatives. For example, consider a call option that grants the owner of the option the right to buy one unit of the second asset at a price of \$10. This option will have a value in state 1 equal to \$10 (the price of the second asset in state 1 reduced by the price that must be paid to acquire asset 1 as provided for by the option, \$10). The value of the option is therefore \$10, the difference between \$20 – \$10 in state 1). In the other two states, the value of the option is zero because the payoff (i.e., the price of the second asset) is no greater than \$10. Hence, it would not be economic for the owner of the option to exercise. Then the price of this call option is

$$\begin{aligned} \text{Price of Call} &= \frac{1}{3} \times (0.3 \times 10) + \frac{1}{3} \times 0 \\ &\quad + \frac{1}{3} \times 0 = 1 \end{aligned}$$

The discount factor prices the assets by taking the expectation under the true probabilities.

Pricing Using Risk-Neutral Probabilities

Alternatively, one can also price the assets under a probability measure known as the *risk-neutral probabilities*. The approach is especially useful for pricing derivatives. The reason is that the risk-neutralized payoffs are easier to determine, while the solution of the discount factor is more complex.

To see how the risk-neutral approach works here, we apply the linear pricing rule given by equation (18) to the risk-free asset. We have:

$$1 = q_1(1 + r) + q_2(1 + r) + \cdots + q_s(1 + r)$$

so that

$$q_1 + q_2 + \cdots + q_s = \frac{1}{1 + r} = q$$

which says the sum of state prices must be equal to the present value of \$1 today. Denote by q the sum of the individual q 's. Since now all the state prices are positive, the ratio of each to q can be considered a probability. Since the ratios sum to one, the probability is well defined. However, this is not the original true probability of the states, but rather some artificial probability, which will be useful in the future for pricing derivatives and other assets.

Suppose now, without loss of generality, that the risk-free asset is the first one. Then the pricing relations for the other assets are

$$\begin{aligned} p_j &= q_1 v_{1j} + q_2 v_{2j} + \cdots + q_s v_{sj} \\ &= \frac{1}{1 + r} \left(\frac{q_1}{q} v_{1j} + \frac{q_2}{q} v_{2j} + \cdots + \frac{q_s}{q} v_{sj} \right) \\ &= \frac{1}{1 + r} E^Q[v_j] \end{aligned} \quad (21)$$

that is, the price is the present value discounted at the risk-free rate of the risk-adjusted expected payoff of the asset, where E^Q denotes the expectation taken under the artificial probability. In other words, for any risky asset, we compute

its value in two steps. In the first step, the risk-neutralized payoff is calculated. In the second step, treating this payoff as riskless, the payoff is discounted at the risk-free rate to obtain the price. Consequently, the artificial probability is also often referred to as the *risk-neutral probability measure*.

For example, for the assets in our previous example, the sum of the state prices is

$$0.1 + 0.2 + 0.2 = \frac{1}{1 + 100\%} = 0.5$$

Moreover, the risk-neutral probabilities are $1/5$, $2/5$, and $2/5$. So the expected payoff of the earlier call option is

$$E^Q(\text{call}) = \frac{1}{5} \times 10 + \frac{2}{5} \times 0 + \frac{1}{5} \times 0 = 2$$

Discounting the \$2 at the risk-free rate (100% in our example), we get the price of \$1 (= \$2/(1 + 1)). This price is, of course, the same as computed above using the discount factor to price the call option.

DISCOUNT FACTOR MODELS

In this section, we provide the discount factor models in a more general setup by allowing the asset returns to be arbitrarily distributed, not necessarily finite states as in the previous section. Then we derive a lower bound on the variance of all possible discount factors, known as the Hansen-Jagannathan bound, and apply it to analyze the implications of some important theories in financial economics.

STOCHASTIC DISCOUNT FACTORS

Consider now a more general problem of an investor who is interested in maximizing utility over the current and future values of consumption,

$$U(C_t, C_{t+1}) = u(C_t) + \delta E[u(C_{t+1})]$$

where the first term is the utility of consumption today, the second term is the utility of fu-

ture consumption, and δ is the subjective time-discount factor of the investor that captures the investor's trade-off between current and future consumption. Note that the second term has an expectation operation since future consumption is unknown today, and the investor can only maximize the expected utility with the expectation taken over all possible random realizations of the future consumption.

Besides the quadratic utility, another popular form of utility function is the power utility

$$u(C_t) = \frac{C_t^{1-\gamma}}{1-\gamma}$$

where γ is the risk-aversion coefficient. The higher the γ , the more risk averse the investor. Typically, a value of γ of about 3 is believed to be reasonable.

For notational brevity, we assume there is only one risky asset, which the pricing relation developed holds for an arbitrary number of assets by adding them into the model. Unlike earlier sections in this entry where finite payoffs were assumed, we now assume the payoff of the risky asset can have an arbitrary probability distribution, so long as the expectation is well defined. The budget constraints for maximizing the utility can be written as

$$\begin{aligned} C_t &= W_t - p_t w \\ C_{t+1} &= W_{t+1} + X_{t+1} w \end{aligned}$$

where W_t and W_{t+1} are the investor's wealth from other sources, w is the number of units of the risky asset the investor purchases today at time t , p_t is the security price, and X_{t+1} is the payoff.

Plugging the budget constraints into the utility function, and taking the derivative with respect to w , we obtain the first-order condition (FOC):

$$p_t u'(C_t) = E_t[\delta u'(C_{t+1}) X_{t+1}]$$

or

$$p_t = E_t[m X_{t+1}], \quad m = \delta \frac{u'(C_{t+1})}{u'(C_t)} \quad (22)$$

This equation says that the price today is the expected value of the discounted payoff, and m

is the discount factor. In the case of the power utility,

$$m = \delta \left(\frac{C_{t+1}}{C_t} \right)^{-\gamma} \quad (23)$$

which is a power function of the consumptions.

What we have derived in equation (22) is called a *consumption-based asset pricing model*, so named because the theory is motivated from the perspective of consumption. This motivation is different from the earlier no-arbitrage arguments that yield equation (18). However, the pricing equations have the same form, except that the discount factor now takes a new specification. Indeed, most, if not all, asset pricing models are of the discount factor form, and different theories may specify the m differently. For the particular specification of m given by equation (22), it is also known as the marginal rate of substitution because it is the ratio of the marginal utilities.

Intuitively, when the marginal rate of substitution is high, the value of future consumption will be high, and an investor is willing to pay more for the asset if the asset's payoff is high in this case. This is why the price, as given by equation (22), is high.

The discount factor representation of asset prices is often also expressed in terms of returns. Let R_t be the gross return on the asset where the gross return is equal to one plus the return. That is, $R_t = X_{t+1}/p_t$. Then the pricing relation in equation (22) is equivalent to

$$1 = E_t[mR_{t+1}] \quad (24)$$

If an asset price is scaled to be equal to \$1, the payoff will be its return, and then the expected discounted return must be equal to \$1, its price today. When there are N risky assets, we can write the discount factor model as

$$1 = E_t[mR_{j,t+1}] \quad (25)$$

where $R_{j,t+1}$ is the return on the asset j .

Note that the expectation in equation (25) is conditional on all available information and therefore the pricing relation is known as the

conditional form of the discount factor model. Taking expectation on both sides of equation (25), we obtain

$$1 = E[mR_{j,t+1}] \quad (26)$$

which is known as the *unconditional form of the discount factor model*. Since conditional implies unconditional, and the reverse is not necessarily true, equation (26) is a weaker form of the model.

Application to CAPM and APT

To see the generality of the discount factor model, consider now its relation to the two dominant equilibrium asset pricing models: the CAPM and APT. As explained shortly, one can write these two asset pricing models as follows:

$$E[R_j] = \tau + \lambda_1 \beta_{j1} + \cdots + \lambda_K \beta_{jK} \quad (27)$$

where R_j is the gross return on asset j , β_{jk} is the beta or risk exposure on the k -th factor f_k , λ_k is the factor risk premium, for $k = 1, 2, \dots, K$, and τ is a constant.

Although equation (27) is now written out in terms of the gross returns to conform with discount factor notations, it can be reduced to have exactly the same expression in terms of returns. For example, the CAPM specifies $K = 1$, τ as the gross risk-free rate $1 + r$, $\lambda_1 = E[R_m] - 1 - r$, and R_m is the gross return on the market portfolio. In this case, λ_1 is same as the usual market return in excess of the risk-free rate since the ones in their difference will be canceled out.

We claim that if, and only if, the stochastic discount factor is a linear function of the factors

$$m = a + b_1 f_1 + \cdots + b_K f_K \quad (28)$$

we will obtain equation (27). Conversely, if equation (27) is true, the discount factor must be a linear function of the factors. Therefore, the CAPM and APT are special cases of the discount factors models.

To see why, it is sufficient to analyze the case of $K = 1$. For simplicity, we drop the subscripts

so that we want to show

$$m = a + bf \quad (29)$$

and

$$E[R_j] = \tau + \lambda\beta_j \quad (30)$$

are equivalent. The latter is often referred to as a *beta pricing model*. In the proof below, we can assume $E[f] = 0$ since we can always move the mean of f into a . Recall the simple statistical formula that the covariance between any two random variables can be written as a sum of the expectation of their product and the product of their expectations

$$\text{Cov}(x, y) = E[xy] + E[x]E[y] \quad (31)$$

Using this formula and $E[f] = 0$, we have, if equation (29) is true,

$$\begin{aligned} 1 &= E[mR_j] = aE[R_j] + bE[fR_j] \\ &= aE[R_j] + b\text{Cov}(R_j, f) - bE[R_j]E[f] \\ &= aE[R_j] + b\text{Cov}(R_j, f) \end{aligned}$$

Solving for $E[R_j]$, we obtain

$$E[R_j] = \frac{1}{a} - \frac{b}{a}\text{Cov}(R_j, f) \quad (32)$$

Comparing this equation with equation (30), it follows that

$$\tau = \frac{1}{a}, \quad \lambda = -\frac{b}{a}\sigma^2(f) \quad (33)$$

where $\sigma^2(f)$ is the variance of the factor. Hence, if the discount factor model is true, it must imply the beta pricing model. Conversely, if the beta pricing model is true, we can solve a and b from equation (33) to get the discount factor model.

Hansen-Jagannathan Bound

As we discussed, an asset pricing model is a specification of the discount factor. The question is what properties all the possible discount factors m must have. Hansen and Jagannathan (1991) show that the variance of the discount factors has to be bounded below. In other

words, m must be volatile enough with respect to the asset returns to be priced.

The discount factor relation, equation (26), ties the return R_t of an asset to its price via the expectation of its product with m . It will be useful to separate R_t out to understand further the relation between m and R_t . Again using the covariance formula, equation (31), we have

$$1 = \text{Cov}[m, R_{t+1}] + E[m]E[R_{t+1}] \quad (34)$$

Suppose that a risk-free asset with gross return $R_f = 1 + r$ is available, where r is the usual risk-free rate. Applying equation (34) to the risk-free asset, the first term will be zero, and hence

$$E[m] = \frac{1}{1+r} \quad (35)$$

Note that this equation is true for all possible discount factors and is an extension of earlier equation (20). In other words, for all possible stochastic discount factors, their mean must be equal to $1/(1+r)$ to price the risk-free asset.

Now we multiply equation (34) by R_f on both sides, and obtain

$$E[R_{t+1}] - R_f = -R_f\text{Cov}[m, R_{t+1}]$$

This says that an asset's return in excess of the risk-free rate will be higher if it has a larger negative covariance with m . Recall that the covariance is related to correlation and standard deviations by

$$\text{Cov}[x, y] = \sigma(x) \times \sigma(y) \times \text{Corr}(x, y)$$

where $\sigma(\cdot)$ denotes the standard deviation function. Since the correlation is always between -1 and 1 , we have from the earlier equation that

$$\begin{aligned} |E[R_{t+1}] - R_f| &= R_f|\text{Cov}[m, R_{t+1}]| \\ &\leq R_f \times \sigma(m) \times \sigma(R_{t+1}) \end{aligned}$$

Separating terms on m from those on R_{t+1} , we have a lower bound on the standard deviation of m as denoted by $\sigma(m)$

$$\frac{\sigma(m)}{E[m]} \geq \frac{|E[R_{t+1}] - R_f|}{\sigma(R_{t+1})} \quad (36)$$

The right-hand side, the ratio of the expected return on a risky asset to its standard deviation, is the Sharpe ratio that measures the extra return beyond the risk-free rate per unit of asset risk. The relationship given by equation (36) says that, for any discount factor that prices the assets, it must have enough variability so that its standard deviation divided by its mean must be greater than the Sharpe ratio of any risky asset in the economy.

The above lower bound on $\sigma(m)$ is known as the *Hansen-Jagannathan bound*. It is an important result since if an asset pricing model fails to pass this bound, then the proposed asset pricing model can be rejected. For example, to test the validity of either the discount factor model given by equation (18) for a finite state economy, or the consumption-based asset pricing given by equation (22), or the CAPM and the APT, one can test first whether it passes the bound given by (36). No further testing will be necessary if it fails the Hansen-Jagannathan bound. Theoretically, Kan and Zhou (2006) show that the Hansen-Jagannathan bound can be tightened substantially with the use of information on the state variables of the stochastic discount factor.

KEY POINTS

- A complete market is one in which any desired payoff in the future can be generated by a suitable portfolio of the existing assets in the economy.
- In a world where the number of states (future scenarios) is finite, a market is complete if and only if this number is equal to the rank of the asset payoff matrix. In particular, it is necessary for the number of assets to be greater than the number of states.
- The law of one price states that any two assets with identical payoffs in the future must have the same price today.
- A linear pricing rule means that the price of a basket of assets is equal to the sum of the prices of those assets in the basket. The law of one price is true if and only if the linear pricing rule is true.
- The state price is the price one has to pay today to obtain a one dollar payoff in a particular future state and nothing in other states. The existence of the state price is equivalent to the validity of the law of one price. It will be unique if the market is in addition complete.
- There are two types of arbitrage opportunities. The first is paying nothing today and obtaining something in the future, and the second is obtaining something today with no future obligations.
- The fundamental theorem of asset pricing asserts the equivalence of three key issues in finance: (1) absence of arbitrage; (2) existence of a positive linear pricing rule; and (3) existence of an investor who prefers more to less and who has maximized utility (no more free lunches to pick up from the economy).
- Due to risk, a rational investor will not pay a price equal to the expected value of an asset and will instead discount it by a suitable factor for compensation for taking on the risk. A stochastic discount factor is a random variable such that the expected value of its product with the asset payoffs is the rational price of the asset. The stochastic discount extends the risk-free discounting (time value of money) to the risky asset case and is the same for pricing all the assets in the economy.
- The CAPM and APT are special cases of stochastic discount factor models in which the discount factor is a linear function of the market factor or APT factors. Moreover, almost all asset models can be formulated as stochastic discount factor models.
- The Hansen-Jagannathan bound provides a simple bound on the variance of a stochastic discount factor, so that one can examine whether the stochastic discount factor satisfies some basic restrictions on the data.

If not, we can reject it without further analysis.

Capital Asset Pricing Models

FRANK J. FABOZZI, PhD, CFA, CPA

Consultant

Abstract: Risk-return analysis in finance is a “normative” theory: It does not purport to describe, rather it offers advice. Specifically, it offers advice to an investor regarding how to manage a portfolio of securities. The investor may be an institution, such as a pension fund or endowment; or it may be an asset management firm with multiple portfolios to manage (e.g., managing various mutual funds and funds for institutional clients). The focus of risk-return analysis is on advice for each individual portfolio. This contrasts with capital asset pricing models, which are hypotheses concerning capital markets as a whole. They are “positive” models, that is, they are hypotheses about that which is—as opposed to “normative” models, which advise on what should be or, more precisely, advise on what an investor should do.

INTRODUCTION

Asset pricing theory seeks to explain how the price or value of a claim from ownership of a financial asset is determined. The pricing or valuation of an asset must take into account the timing of the payments expected to be received and the risk associated with receiving the expected payments. The major challenge in asset pricing theory is often not the timing issue but the treatment of risk. The formulation of an asset pricing theory that has empirically proven to have good predictive value offers investors the opportunity to capitalize on mispriced assets. Moreover, the theory provides investors with a tool for pricing new financial instruments and nonpublicly traded assets.

Cochrane (2001) suggests two popular approaches to asset pricing: absolute pricing and

relative pricing. The absolute pricing approach seeks to price an asset by reference to its exposure to fundamental macroeconomic risk. An example of an absolute pricing approach is the consumption-based capital asset pricing model (CAPM) formulated by Breeden (1979). In contrast, the relative pricing approach seeks to value an asset based only on the prices of other assets without reliance on the exposure of the asset to the various sources of macroeconomic factors. The well-known option pricing model formulated by Black and Scholes (1973) is an example of an asset pricing model that employs the relative pricing approach.

Most asset pricing models used in practice today are the result of a blend of both approaches. *Capital asset pricing models* (CAPM), the subject of this entry, are an example. The CAPM starts

as an absolute pricing model but then, as will be explained, prices assets relative to the market. There is no attempt in the CAPM to determine how the market risk premium or the risk factor is determined in an economy.

In this entry, we focus on the basic CAPM first formulated in the 1960s by several academicians. There have been numerous extensions of the basic CAPM that have been proposed in the decades that followed but these will not be covered in this entry. However, because there is considerable confusion regarding certain aspects of the theory, in addition to describing the basic CAPM in this entry we explain the sources of the confusion and their implications.

SHARPE-LINTNER CAPM

The first CAPM was that of Sharpe (1964) and Lintner (1965). The *Sharpe-Lintner CAPM* (SL-CAPM) assumes the following:

- All investors have the same beliefs concerning security returns.
- All investors have mean-variance efficient portfolios.
- All investors can lend all they have or can borrow all they want at the same risk-free interest rate that the U.S. federal government pays to borrow money.

By the mean it is meant the expected value of the return of a security or portfolio. Thus, throughout this entry, we use the terms “mean return” and “expected return” interchangeably. By variance, we mean the variance of the returns of a security or portfolio. This is the square of the standard deviation, the most commonly used measure in statistics to quantify the dispersion of the possible outcomes of some random variable. Standard deviation is the more intuitively meaningful measure: Most of any probability distribution is between its mean mi-

nus two standard deviations and mean plus two distributions. It is not true that most of a distribution is between the mean and plus or minus two variances, or any other number of variances. While standard deviation is the more intuitive measure, formulas are more conveniently expressed in terms of variance. One can most easily compute the variance of a portfolio and then take its square root to obtain its standard deviation.

By *mean-variance efficient portfolios*, we mean that of all the possible portfolios that can be created from all of the securities in the market, the ones that have highest mean for a given variance.

The two major conclusions of the SL-CAPM are:

CAPM Conclusion 1. The market portfolio is a mean-variance efficient portfolio.

CAPM Conclusion 2. The difference between the expected return and the risk-free interest rate, referred to as the *excess return*, of each security is proportional to its *beta*.

The “market portfolio” includes all securities in the market. The composition of the portfolio is such that the sum of the weights allocated to all the securities is equal to one. That is, denoting X_i^M as the percentage of security i in the market portfolio (denoted by M), then

$$\sum_{i=1}^n X_i^M = 1 \quad (1)$$

Each holding of a security is proportional to its part of the total market capitalization. That is,

$$X_i^M = \frac{\text{Market value of } i\text{-th security}}{\text{Total market value of all securities}} \quad (2)$$

CAPM Conclusion 1 is that this “market portfolio” is on the mean-variance efficient frontier.

Let r_i stand for the return on the i -th security during some period. The return on the market

portfolio then is

$$r^M = \sum_{i=1}^n X_i^M r_i \quad (3)$$

The beta (β) referred to in CAPM Conclusion 2 can be estimated using regression analysis from historical data on observed returns for a security and observed returns for the market. In this regression analysis, security return is the “dependent variable” and market return is the “independent variable.” However, the beta produced by this analysis should be interpreted as a measure of association rather than causation. That is, it is a measure of the extent that the two quantities move up and down together, not as the so-called “independent variable” causing the level of the “dependent variable.” Below we examine why there is this association (not causation) in CAPM between security returns and market return.

The excess return, denoted by e_i , is the difference between the security’s expected return, $E(r_i)$, and the risk-free interest rate, r_f , at which all investors are assumed to lend or borrow:

$$e_i = E(r_i) - r_f \quad (4)$$

CAPM Conclusion 2 is that the excess return for security i is proportional to its β . That is, letting k be a constant then

$$e_i = k\beta_i \quad i = 1, \dots, n \quad (5)$$

It can also be shown that equation (5) applies to portfolios as well as individual securities. Thus in an SL-CAPM world, each security and portfolio has an excess return that is proportional to the regression of the security or portfolio’s return against the return of the market portfolio.

ROY CAPM

A second CAPM, which appeared shortly after that of the writings of Sharpe and Lintner, differs from the SL-CAPM only in its assumption

concerning the investment constraint imposed by investors. More specifically, it assumes that each investor (I) can choose any portfolio that satisfies

$$\sum_{i=1}^n X_i^I = 1 \quad (6)$$

without regard to the sign of the variables. Positive X_i^I is interpreted as a long position in a security while a negative X_i^I is interpreted as a short position in a security.

However, a negative X_i^I is far from a realistic model of real-world constraints on shorting. For example, equation (6) would consider feasible a portfolio with

$$\begin{aligned} X_1 &= -1,000 \\ X_2 &= 1,001 \\ X_i &= 0 \quad i = 3, \dots, n \end{aligned}$$

since the above sums to one. This would correspond to an investor depositing \$1,000 with a broker; shorting \$1,000,000 of stock 1; then using the proceeds of the sale, plus the \$1,000 deposited with the broker to buy \$1,001,000 worth of stock 2. In fact, in this example, Treasury Regulation T (Reg T) would require that the sum of long positions, plus the value of the stocks sold short, not exceed \$2,000.

Equation (6), as the only constraint on portfolio choice, was first proposed by Roy (1952), albeit not in a CAPM context. Since it is difficult to pin down who first used this constraint set in a CAPM (more than one did so almost simultaneously), we refer to this as the *Roy CAPM* as distinguished from the SL-CAPM.

CONFUSIONS REGARDING THE CAPM

Probably no other part of financial theory has been subject to more confusion, by

professionals and amateurs alike, than the CAPM. Major areas of confusion include the following:

Confusion 1. Failure to distinguish between the following two statements:

The market is efficient in that each participant has correct beliefs and uses them to their advantage.

and

The market portfolio is a mean-variance efficient portfolio.

Confusion 2. Belief that equation (5) shows that CAPM investors get paid for bearing “market risk.” That this view—held almost universally until quite recently—is in error is easily demonstrated by examples in which securities have the same covariance structure but different excess returns.

Confusion 3. Failure to distinguish between the beta in Sharpe’s one-factor model of covariance (see Sharpe, 1963) and that in Sharpe’s CAPM.

The following sections present the assumptions and conclusions of the SL-CAPM and the Roy CAPM, and discuss the nature of these three historic sources of confusion, and their practical implications.

TWO MEANINGS OF MARKET EFFICIENCY

CAPM is an elegant theory. With the aid of some simplifying assumptions, it reaches dramatic conclusions about practical matters. For example:

- How can an investor choose an efficient portfolio? The answer: Just buy the market.
- How can an investor forecast expected returns? The answer: Just forecast betas.
- How should an investor price a new security? The answer is once again: Forecast its beta.

CAPM’s simplifying assumptions make it easier to deduce properties of market equilib-

ria, which is like computing falling body trajectories while assuming there is no air. But, before betting the ranch that the feather and the brick will hit the ground at the same time, it is best to consider the implications of some of the omitted complexities. The present section mostly explores the implications of generalizing one of the CAPMs’ simplifying assumptions.

Note the difference between the statement “The market is efficient,” in the sense that market participants have accurate information and use it correctly to their benefit, and the statement “The market portfolio is a mean-variance efficient portfolio.” Under some assumptions the two statements are equivalent. Specifically, if we assume:

Assumption 1. Transaction costs and other illiquidities can be ignored.

Assumption 2. All investors hold mean-variance efficient portfolios.

Assumption 3. All investors hold the same (correct) beliefs about means, variances, and covariances of securities.

Assumption 4. Every investor can lend all she or he has or can borrow all she or he wants at the risk-free interest rate.

Then based on these four assumptions we get CAPM Conclusion 1: The market portfolio is a mean-variance efficient portfolio. This CAPM conclusion also follows if Assumption 4 is replaced by the following assumption:

Assumption 4’. Equation (6) is the only constraint on the investor’s choice of portfolio.

As noted earlier, a negative X_i is interpreted as a short position; but this is clearly a quite unrealistic model of real-world short constraints. Equation (6) would permit any investor to deposit \$1,000 with a broker, sell short \$1,000,000 worth of one security, and buy long \$1,001,000 worth of another security.

In addition to CAPM Conclusion 1, Assumptions 1 through 4 imply CAPM Conclusion 2: In equilibrium, excess returns are proportional to betas, as in equation (5). This CAPM

Table 1 Expected Returns and Standard Deviations for Three Hypothetical Securities^a

Security	Expected Return	Standard Deviation
1	0.15%	0.18%
2	0.10%	0.12%
3	0.20%	0.30%

^aSecurity returns are uncorrelated.

conclusion is the basis for the CAPM’s prescriptions for risk adjustment and asset valuation.

Since a Roy CAPM world may or may not have a risk-free asset, Assumptions 1–3 plus Assumption 4’ cannot imply CAPM Conclusion 2. These assumptions do, however, imply the following:

CAPM Conclusion 2’. Expected returns are a linear function of betas, that is, there are constants, a and b , such that

$$E(r_i) = a + b\beta_i \quad i = 1, \dots, n \quad (7)$$

Equation (5) of the SL-CAPM is the same as equation (7) of the Roy CAPM with $a = r_f$.

CAPM Conclusions 1 and 2 (or 2’) do not follow from Assumptions 1, 2, and 3 if 4 (or Assumption 4’) is replaced by a more realistic description of the investor’s investment constraints. This is illustrated by an example with the expected returns and standard deviations given in Table 1. In this example, it is assumed that the returns are uncorrelated (but similar results occur with correlated returns). The example assumes that investors cannot sell short or borrow. The same results hold if investors can borrow limited amounts or can sell short but are subject to Reg T or a similar constraint.

Assumptions 1 through 3 are assumed in this example. Rather than Assumption 4 or Assumption 4’, the example assumes that the investor can choose any portfolio that meets the following constraints:

$$X_1 + X_2 + X_3 = 1.0 \quad (8a)$$

and

$$X_1 \geq 0, X_2 \geq 0, X_3 \geq 0 \quad (8b)$$

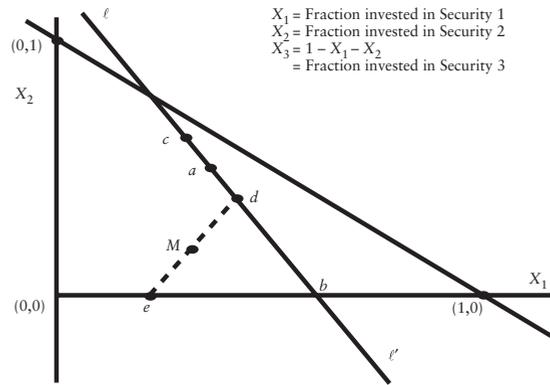

Figure 1 Example Illustrating That When Short Sales Are Not Allowed, the Market Portfolios Are Typically Not Mean-Variance Efficient

This is the “standard” portfolio selection constraint set presented in Markowitz (1952). It differs from the Roy constraint set in the inclusion of nonnegativity constraints, the inequalities given by (8b).

In Figure 1, X_1 —the fraction invested in Security 1—is plotted on the horizontal axis; X_2 —the fraction invested in Security 2—is plotted on the vertical axis; and X_3 —the fraction invested in the third security—is given implicitly by the relationship $X_3 = 1 - X_1 - X_2$. In the figure, the portfolio labeled “c” has smaller variance than any other portfolio that satisfies the equation (8a) constraint. In general, such a minimum-overall-variance portfolio may or may not satisfy the inequalities given by (8b) constraints. In other words, the minimum-overall-variance portfolio may or may not be feasible for the original Markowitz constraint set (Markowitz, 1952). In the present example it is. Results similar to those we illustrate here also typically hold when c is not feasible for the standard model.¹

The line ll' connects all points (portfolios) that minimize variance, on the portfolio-as-a-whole, for various levels of portfolio expected return, subject to equation (8a), ignoring non-negativity inequalities (8b). Using differential calculus, one can minimize a function such as

$$V = \sum_{i=1}^3 X_i^2 V_i \quad (9a)$$

subject to constraints

$$\sum_{i=1}^3 X_i = 1 \quad (9b)$$

$$E_0 = \sum_{i=1}^3 X_i E(r_i) \quad (9c)$$

One can do so with the expected returns and standard deviations from Table 1, letting E_0 vary, and thereby obtain the line in Figure 1. Moving downward and to the right on $\ell\ell'$, the portfolio expected return increases. This downward direction for increasing expected return does not always hold: It depends on the choice of security expected returns.

In the Roy model, every point in the figure is feasible since they all satisfy equation (6) or, equivalently, equation (8a). It follows that, in the Roy CAPM, *all* points on $\ell\ell'$, from “ c ” downward in the direction of increasing E , are efficient. But in the standard model, including nonnegativity inequalities (8b), all points on $\ell\ell'$ below the point “ b ” are not feasible (since they have negative X_2) and therefore cannot be efficient. In this example, when portfolio choice is subject to the standard constraint set, the set of efficient portfolios is the same as that of the Roy constraint set from portfolio c to portfolio b . After that, the set of efficient portfolios moves horizontally along the X_1 axis, ending at point $(0, 0)$. This represents the portfolio with everything invested in Security 3, which has maximum expected return in the example.

Suppose that some investors select the cautious portfolio d , while the remainder selects the more aggressive portfolio e . The market portfolio M lies on the straight line that connects d and e (e.g., halfway between if both groups have equal amounts invested).

But M is not an efficient portfolio, either for the standard constraint set or for the Roy constraint set. Thus, even though all investors hold mean-variance efficient portfolios, the market portfolio is not mean-variance efficient!

A Simple Market

Figure 1 demonstrates that if the expected returns and variances for our three hypothetical securities in Table 1 reflect equilibrium beliefs, then the market portfolio would not be a mean-variance efficient portfolio. But can these be equilibrium beliefs? Consider the following simple market: Inhabitants of an island live on coconuts and produce them from their own gardens. The island has three enterprises, namely, three coconut farms. Once a year, a stock market convenes to trade the shares of the three farms. Each year the resulting share prices turn out to be the same as those of preceding years. Thus the only source of uncertainty of return is the dividend each stock pays during the year, which is the stock’s pro rata share of the farm’s production. Markowitz (2005) shows that means, variances, and covariances of coconut production exist that imply the efficient set in Figure 1, or in any of the other three security-efficient sets presented in Markowitz (1952 and Chapter 7 in 1959) initial works.

With such probability distributions of returns, the market is rational in the sense that each participant knows the true probability distribution of returns, and each seeks and achieves mean-variance efficiency. Nevertheless, in contrast to the usual CAPM conclusion, the market portfolio is not an efficient portfolio. It also follows that there is no representative investor since no one wants to hold the market portfolio.

Arbitrage

Suppose that most investors are subject to the nonnegativity requirement of inequalities (8b), but one investor can short in the CAPM sense. (Perhaps the CAPM investor has surreptitious access to a vault containing stock certificates that he or she can “borrow” temporarily without posting collateral.) Would this CAPM investor, with unlimited power to short and use the proceeds to buy long, arbitrage away the inefficiency in the market portfolio?

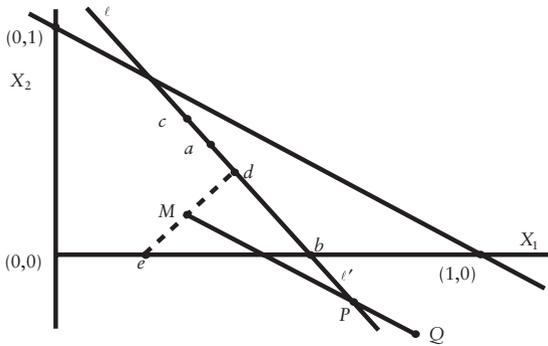

Figure 2 Illustration That an Investor Who Can Sell Short and Use the Proceeds to Buy Long Should Not Short an Inefficient Market

Figure 2 shows an investor would not do so. Suppose that portfolio P is the one most preferred by the Roy CAPM investor. If this investor shorts M and uses the proceeds to buy more P , then the resulting portfolio will be on the straight line connecting M and P —but this time on the far side of P (e.g., at Q) rather than between M and P . But Q is not efficient for the Roy CAPM investor since it does not lie on the ll' line. The Roy CAPM investor is better off just holding P rather than shorting M to buy more P .

With market participants holding portfolios d , e , and P and with the weighted average of the d and e investors being at M , the new market portfolio will be on the straight line between M and P , such as at M^a , M^b , or M^c in Figure 3.

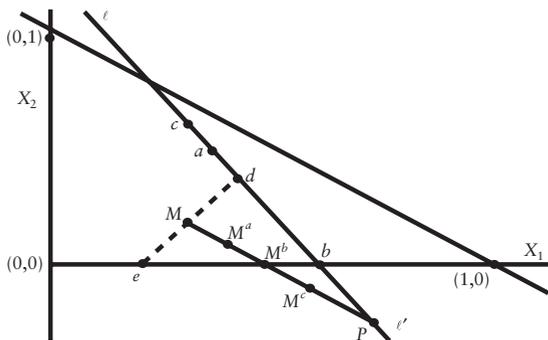

Figure 3 Illustration That the Presence of a CAPM Short Seller Does Not Make the Market Portfolio Efficient

M^c cannot be the market equilibrium since this would imply a negative market value for Security 2. Similarly, M^b implies a zero market value for Security 2, therefore a zero price.

Thus the only points (portfolios) between M and P that are consistent with positive prices for all securities lie strictly between M and M^b , such as M^a ; but M^a is not efficient for the investors with either a standard or a Roy constraint set.

Expected Returns and Betas

If Assumptions 1 through 4 (or Assumption 4') are true, then CAPM Conclusion 2' follows: Expected returns are linearly related to the betas of each security as in equation (7), that is,

$$E_1 = a + b\beta_1$$

$$E_2 = a + b\beta_2$$

$$E_3 = a + b\beta_3$$

where β_i is the coefficient of the regression of the return on the i th security against the return on the market portfolio. In other words, all (E_i, β_i) combinations lie on the straight line

$$Y = a + bX$$

But equation (7) does not typically hold if Assumptions 1 through 3 are true but neither Assumption 4 nor Assumption 4' is also true, as illustrated using the data in Tables 2 and 3, and Figure 4. Table 2 shows the β_i for portfolio P ; Table 3 shows them for portfolio M . These betas are computed using the fact that the regression coefficient $\beta_{s,r}$ of random variable s against a random variable r is

$$\beta_{s,r} = \frac{\text{Covariance}(r, s)}{\text{Variances}(s)} \tag{10}$$

Table 2 Betas versus Portfolio P

Security	Percent in P	cov _{i,P} = P _i V _i	beta _{i,P}
1	0.70%	0.0227	0.52
2	-0.25	-0.0036	-0.08
3	0.55	0.0495	1.12

Note: var(P) = 0.0440; beta_{i,P} = cov_{i,P} / var(P).

Table 3 Betas versus Portfolio M

Security	Percent in M	$cov_{i,M} = M_i V_i$	$\beta_{i,M}$
1	0.30	0.0097	0.36
2	0.19	0.0027	0.10
3	0.51	0.0459	1.71

Note: $\text{var}(M) = 0.0268$; $\beta_{i,M} = \text{cov}_{i,M} / \text{var}(M)$.

Figure 4 shows the plot of these betas against the expected returns given in Table 1. The relationship between beta and expected return is linear for regressions against P , as implied by equation (7), but not against M . In general, expected returns are a linear function of betas if and only if the regressions are against a portfolio on the $\ell\ell'$ line. (See Chapter 12 in Markowitz and Todd [2000].)

Limited Borrowing

Thus far we have seen that the market portfolio is not necessarily an efficient portfolio, and there is usually no linear relationship between expected returns and betas (regressions against the market portfolio) if the SL-CAPM or Roy CAPM is replaced by the standard, Markowitz constraint set, constraints given by (8). Figure 5 illustrates that the same conclusions hold if borrowing and lending at a risk-free interest rate are permitted, but borrowing is limited, for example, to 100% of the equity in the portfolio. In Figure 5, Security 3 is the risk-free asset.

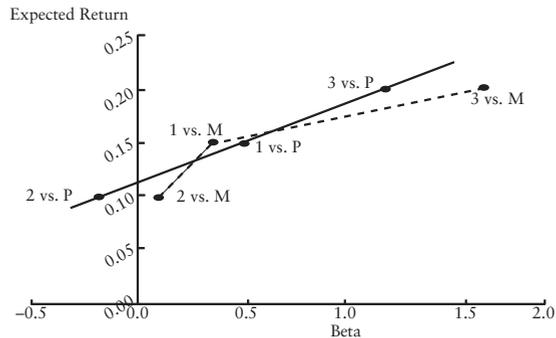

Figure 4 Linear Relationship between Expected Returns and Betas If and Only If the Regression Is Against a Portfolio on the Line $\ell\ell'$ in Figure 1.

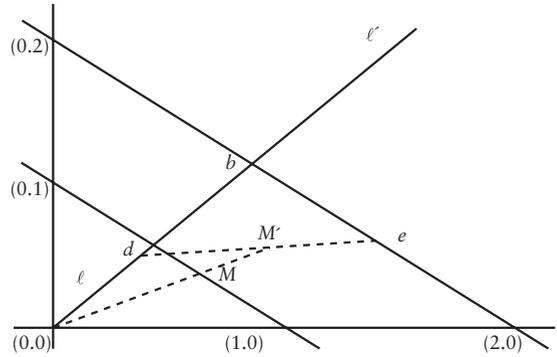

Figure 5 Illustration That If Borrowing Is Permitted but Limited, the Market Portfolio Is Still Typically Not an Efficient Portfolio

With 100% borrowing permitted, the set of feasible portfolios is no longer on and in the triangle with $(0, 0)$, $(1, 0)$, and $(0, 1)$ as its vertices. Rather, the feasible region is on and in the triangle whose vertices are $(0, 0)$, $(2, 0)$, and $(0, 2)$. For example, the $(2, 0)$ point represents the portfolio with 200% invested in Security 1.

In the SL-CAPM, the efficient set starts at the portfolio $(0, 0)$, which holds only the risk-free asset. From there, the efficient set moves along a straight line in the first quadrant of Figure 5.² In the SL-CAPM, this efficient line would continue in the same direction without limit. In the model with borrowing limited to at most 100% of equity, the ray extending from $(0, 0)$ is no longer feasible (therefore no longer efficient) when it crosses the line connecting $(0, 2)$ and $(2, 0)$ —at b in the figure. The efficient set then moves towards the leveraged portfolio with highest expected return: $(2, 0)$ in the present case. Thus in Figure 5 the set of efficient portfolios is the line segment connecting $(0, 0)$ to b , followed by the segment connecting b to $(2, 0)$. As in our analysis using the standard constraint set, if some investors hold portfolio d and the remainder hold portfolio e , then the “market portfolio” will be between them (e.g., at M') and will not be an efficient portfolio.

We put “market portfolio” in quotes above because M' is a leveraged portfolio. In order to meet the definition of market portfolio in

equation (1), so that the holdings in the market portfolio sum to one, we must rescale M' . This gives us the market portfolio (no quotation marks) M , which is also not an efficient portfolio.

Finally, as in the analysis of the standard case since M is not on the $\ell\ell'$ line, there does not exist a linear relationship between expected returns and betas. Also, there is no “representative investor,” since no investor wants to hold the market portfolio.

Further Generalizations

Suppose that there are n securities (for $n = 3$ or 30 or $3,000$). Suppose that one security has the highest expected return, and that the n securities have a “nonsingular covariance matrix.” This means that there is no riskless combination of risky securities. If the only constraint on the choice of portfolio is equation (6), then the portfolios that minimize portfolio variance V_p for various values of portfolio expected return E_p lie on a single straight line in n -dimensional portfolio space. This is not true for an investor also subject to nonnegativity constraints such as in the inequalities given by (8b).

The *critical line algorithm* (CLA) for tracing out all efficient portfolios begins with the portfolio that is 100% invested in the security with highest expected return (see Markowitz and Todd, 2000). It traces out the set of efficient portfolios in a series of iterations. Each iteration computes one piece (one linear segment) of the piecewise linear efficient set. Each successive segment has either one more or one less security than the preceding segment. If the universe consists of, say 10,000 securities, and if all securities are to be demanded by someone, then this universal efficient frontier must contain at least 10,000 segments. If investors have sufficiently diverse risk tolerances, they will choose portfolios on many different segments. The market portfolio is a weighted average of individual portfolios and typically will not be on any efficient segment.

This characterization of efficient sets remains true if limited borrowing is allowed, as we saw.

It also remains true when short selling is permitted but is subject to Reg T or a similar constraint (see Jacobs, Levy, and Markowitz, 2005).

CAPM INVESTORS DO NOT GET PAID FOR BEARING RISK

Recall that if the SL-CAPM assumptions are made, then a stock’s beta (regression against the market portfolio) is proportional to its excess return, as shown in equation (5). Markowitz shows that this does *not* imply that CAPM investors are paid to bear risk (see Markowitz, 2008).

This is most easily seen if we assume that risks are uncorrelated. (CAPM should cover this case, too.) In this case, we show that two securities can have the same variance but different expected returns, or the same expected returns and different variances. Therefore, it cannot be true that the investor is paid for bearing risk!

According to equation (10), the beta of r_i against r_M is

$$\beta_i = \frac{\text{Covariance}(r_i, r^M)}{\text{Variance}(r^M)}$$

Therefore, equation (5) holds if and only if we also have

$$e_i = \tilde{b} \text{covariance}(r_i, r^M) \quad (11)$$

where

$$\tilde{b} = b/\text{Var}(r^M)$$

In other words, excess return is proportional to β_i if and only if it is proportional to the covariance between r_i and r^M .

As a calculus exercise one can show that, in the uncorrelated case, the SL-CAPM investor minimizes portfolio variance for given portfolio mean if and only if the investor chooses a portfolio such that

$$VX_i^l = k^l e_i \quad (12a)$$

where V_i is the variance of r_i and k^l depends on the investor's risk aversion.

Equation (12a) implies a similar relationship for the market portfolio:³

$$V_i X_i^M = k^M e_i \quad (12b)$$

Therefore,

$$X_i^M = k^M \left(\frac{e_i}{V_i} \right) \quad \text{for } i = 1, \dots, n \quad (12c)$$

Thus if two securities have the same positive excess return but different variances, the market portfolio will contain a larger dollar value of the one with the lower variance. Conversely, if two securities have the same variance but different positive excess returns, the market portfolio will contain a larger dollar value of the one with the higher excess return.

Now let us consider where the linear relationship in equation (5), or (11), comes from in this case of uncorrelated returns. It can be shown that in equation (12b), $V_i X_i^M$ is the covariance of the r_i with the market. Therefore, covariance with the market is proportional to excess return (and vice versa) because the security with the higher ratio of excess return to variance is a larger part of the market portfolio.

Thus, in the uncorrelated case, the relationship between beta and excess return in equation (5) results from the security with higher excess return (per unit variance) being a larger part of the market portfolio. The beta in equation (5) is the regression of r_i against the market portfolio and, in the uncorrelated case, the only security in the market portfolio with which it is correlated is itself.

When returns are correlated, the formula for the covariance between security return and market portfolio return is more complicated, but the basic principle is the same. For example, if two securities have the same covariance structure, the one with the higher expected return will constitute a larger share of the market portfolio—despite the presence in the market portfolio of securities with which it is correlated—and hence have its own re-

turns more correlated with returns on the market portfolio.

THE “TWO BETA” TRAP

Two distinct meanings of the word “beta” are used in modern financial theory. These meanings are sufficiently alike for people to converse—some with one meaning in mind, some with the other—without realizing they are talking about two different things. The meanings are sufficiently different, however, that one can validly derive diametrically opposite conclusions depending on which one is used. The net result of all this can be like an Abbott and Costello vaudeville comedy routine with portfolio theory rather than baseball as its setting. This is what Markowitz (1984) calls the *two beta trap*. Below we first review the background of the two betas and then tabulate propositions that are true for one concept and false for the other.

Beta₁₉₆₃

Sharpe's *single-index* (or one-factor) model of covariance introduced in 1963 assumes that the returns of different securities are correlated with each other because each is dependent on some underlying systematic factor (see Sharpe, 1963). This can be written as

$$r_i = \alpha_i + \beta_i F + u_i \quad (13)$$

where the expected value of u_i is zero, and u_i is uncorrelated with F and every other u_j .

Originally F was denoted by I and described as an “underlying factor, the general prosperity of the market as expressed by some index.” We have changed the notation from I to F to emphasize that r_i depends on the underlying factor rather than the index used to estimate the factor. The index never measures the factor exactly, no matter how many securities are used in the index, provided that each security has positive

variance of u_i , since the index I equals:

$$\begin{aligned} I &= \sum w_i r_i \\ &= \sum \alpha_i w_i + F(w_i \beta_i) + \sum u_i w_i \\ &= A + BF + U \end{aligned} \quad (14)$$

where w_i is the weight of return r_i in the index, and

$$\begin{aligned} A &= \sum \alpha_i w_i \\ B &= \sum w_i \beta_i \\ U &= \sum u_i w_i \end{aligned}$$

U is the error in the observation of F . Under the conditions stated, the variance of U is

$$V_U = \sum_{i=1}^N w_i^2 V_{u_i} > 0 \quad (15)$$

Sharpe (1963) tested equation (13) as an explanation of how security returns tend to go up and down together. He concluded that equation (13) was as complex a model of covariance as seemed to be needed. This conclusion was supported by research of Cohen and Pogue (1967). King (1966) found strong evidence for industry factors in addition to the market-wide factor. Rosenberg (1974) found other sources of systematic risk beyond the market-wide factor and industry factors.

We refer to the beta coefficient in equation (13) as “beta₁₉₆₃” since it is the subject of Sharpe’s 1963 article. We contrast the properties of this beta with that of the beta that arises from the Sharpe-Lintner CAPM. The latter we will refer to as “beta₁₉₆₄” since it is the subject of Sharpe (1964).

Beta₁₉₆₄

We noted that the SL-CAPM makes various assumptions about the world, including that all investors are mean-variance efficient, have the same beliefs, and can lend or borrow all they want at the same “risk-free” interest rate. Note, however, one assumption that the SL-CAPM

does *not* make is that the covariances among securities satisfy equation (13). On the contrary, the assumptions it makes concerning covariances are quite general.⁴ They are consistent with equation (13) but do not require it. They are also consistent with the existence of industry factors as noted by King, or other sources of systematic risk such as those identified by Rosenberg.

As previously noted, the beta that appears in the CAPM relationship of equation (5) (which we now refer to as beta₁₉₆₄) is the regression of the i th security’s return against the return on the market portfolio. This is defined whether or not the covariance structure is generated by the single-factor model of equation (13). Equation (5) is an assertion about the expected return of a security and how it relates to the regression of the security’s return against the market-portfolio return. Unlike equation (13), it is not an assertion about how security returns covary.

One source of confusion between beta₁₉₆₃ and beta₁₉₆₄ is that William Sharpe presented each of them. Sharpe, however, has never been confused on this point. In particular, when explaining beta₁₉₆₄ he emphasizes that he derived it without assuming equation (13).

Propositions about Betas

Table 4 lists various propositions about betas and indicates whether they are true or false for beta₁₉₆₃ or beta₁₉₆₄. The first column presents each proposition, the second indicates whether the proposition is true or false for beta₁₉₆₃, and the third column indicates the same for beta₁₉₆₄. Most of the propositions in Table 4 are true for one of the betas and false for the other.

Proposition 1

Because of the definition of a regression beta in general, both beta₁₉₆₃ and beta₁₉₆₄ equal

$$\beta_i = \text{cov}(r_i, R) / V(R)$$

for some random variable R . In the case of beta₁₉₆₃, R is F for equation (13); in the case of beta₁₉₆₄, R is the M in equations (1) and (2).

Table 4 Propostions about Beta

	β_{1963}	β_{1964}
1. The β_i of the i th security equals $\text{cov}(r_i, R)/V(R)$ for some random variable R .	T	T
2. R is “observable”; specifically, it may be computed exactly from security returns (r_i) and market values (X_i).	F	T
3. R is a <i>value</i> -weighted average of the (r_i).	F	T
4. An index I that estimates R should ideally be weighted by a combination of ($1/V_{u_i}$) and (β_i/V_i). Unfortunately, the β_i and V_{u_i} needed to determine these weights are unobservable.	T	F
5. If ideal weights are not used, then equal weights are “not bad” in computing I ; specifically, nonoptimum weights can be compensated for by increased sample size.	T	F
6. Essentially, all that is important in computing I is to have a large number of securities; it is not necessary to have a large fraction of all securities.	T	F
7. The ideally weighted index is an efficient portfolio.	F	T

Proposition 2

Equation (15) implies that F cannot be observed exactly no matter how many securities are used to estimate it, provided that no security has a zero variance of u_i . In contrast, portfolio M in equation (2) is observable, at least in principle, if only we are diligent enough to measure each X_i^M in the market. Thus, the assertion that R is observable is true in principle for β_{1964} and false for β_{1963} .

Propositions 3 and 4

One source of confusion about the two betas concerns whether an index estimating R should be “value weighted”; that is, should the w_i used in computing an estimate of R from the r_i equal the X_i^M ? We have seen that in the case of β_{1964} :

$$R = \sum X_i^M r_i$$

In this case $W_i = X_i^M$ = market-value weights.

The answer is different in the case of β_{1963} . Ideally, we would like to eliminate the error term U from equation (14). Our index would be perfect if $V_U = 0$, provided of course $B \neq 0$. Nevertheless, as long as no security has $V_{u_i} = 0$, the perfect index cannot be achieved with a finite number of securities. Short of this, it might seem that the best to be wished is that V_U be a minimum. In this case, w_i would equal $1/V_{u_i}$. The optimum choice of weights for estimating

the underlying factor F is more complicated, depending also on β_i/V_i (see Markowitz, 1983) and more complicated still, since V_{u_i} and β_i are not known.

Proposition 5

The fifth proposition in Table 4 asserts that if ideal weights cannot be obtained, equal weights are good enough. In particular, an increase in the number of securities can compensate for nonoptimum weights. We have already seen that this proposition is false for β_{1964} . It is easily seen to be true for β_{1963} under mild restrictions on how fast the V_{u_i} increases as i increases.

Proposition 6

The next proposition asserts that all that is important in designing a good index is to have many securities, as opposed to having a large percentage of the population represented in the index. This proposition is true for I_{1963} and false for I_{1964} , as may be illustrated by two extreme examples.

First, suppose that there are only a few securities in the entire population, and all of them are used in computing a value-weighted index. Then I_{1964} would, in fact, be M and would be precisely correct. In the case of I_{1963} , on the other hand, equation (15) implies that if $n = 6$, for example, the error term V_U is the same

regardless of whether the six securities are 100% or 1% of the universe.

At the other extreme, imagine that the sample is large but is a small percentage of the total population. For example, suppose $N = 1,000$ out of 100,000 securities. Then I_{1963} will give a good reading for F , and therefore β_{1963} , but I_{1964} may lead to serious misestimates of β_{1964} . First, the covariance with I_{1964} of an asset not in this index will tend to be too low. Second, if the index contains more of certain kinds of assets than is characteristic of the entire population, then assets of this sort will tend to have a higher correlation with the index than with the true M , and assets of other sorts will tend to have lower correlations. More precisely, the covariance between return r_i and the market is a weighted average of the covariances σ_{ij} (including $V_i = \sigma_{ii}$) weighted by market values. If the index chosen does not have approximately the same average σ_{ij} for a given i , the estimates of $\beta_{i,1964}$ will be in error.

Proposition 7

This proposition asserts that the ideal index is an efficient portfolio. This is true for I_{1964} and false for I_{1963} since one of the conclusions of the SL-CAPM assumptions is that the market portfolio is efficient. In fact, the market portfolio is the only combination of risky assets that is efficient in this CAPM. All other efficient portfolios consist of either investment in the market portfolio plus lending at the risk-free rate, or of investment in the market portfolio financed in part by borrowing at the risk-free rate. On the other hand, β_{1963} has nothing to do with expected returns or market efficiency.

KEY POINTS

- The two major conclusions of the Sharpe-Lintner CAPM are that (1) the market portfolio is a mean-variance efficient portfolio; and (2) the excess return of each security is proportional to its beta.
- The “market portfolio” includes all securities in the market.
- The beta (β) in the CAPM is estimated using regression analysis using historical data on observed returns for a security (response variable) and observed returns for the market (explanatory variable).
- The Roy CAPM differs from the Sharpe-Lintner CAPM only in its assumption concerning the investment constraint imposed by investors. More specifically, it assumes that each investor can short securities.
- Confusion regarding the CAPM involves (1) the failure to distinguish between the following two statements: The market is efficient in that each participant has correct beliefs and uses them to their advantage on the one hand, and the market portfolio is a mean-variance efficient portfolio on the other hand; (2) belief that CAPM investors get paid for bearing nondiversifiable risk; and (3) failure to distinguish between the beta in Sharpe’s one-factor model of covariance (1963 beta) and that in Sharpe’s CAPM (1964 beta).

NOTES

1. Markowitz presents examples of three-security standard analyses in which “ c ” is feasible in some cases and not feasible in others. It is possible in the latter case for the set of mean-variance efficient portfolios to be a single line segment or even a single point. But typically, when “ c ” is outside of the feasible triangle, as well as when it is within it, the set of efficient portfolios consists of two or more line segments (the “efficient segments”), which meet at “corner portfolios.” Thus the construction in Figure 1 can typically be carried out in cases in which “ c ” is not feasible. (See Markowitz, 1952.)
2. The SL-CAPM requires nonnegative investments. Thus if the parameters of an example were such that the straight line would move into, say, the fourth quadrant, X_2 would equal zero on the line and would, in

effect, drop out of the market, and out of the analysis.

3. If we multiply both sides of equation (12a) by w^l , the l -th investor's equity as a fraction of total market equity, and sum we get

$$V_i \left(\sum_l w^l X_i^l \right) = \left(\sum_l w^l k^l \right) e_i$$

If we sum the above over all securities, the second factor on the left, namely

$$S = \sum_i \left(\sum_l w^l X_i^l \right)$$

will not necessarily sum to one since nothing in the SL-CAPM assumptions prevents market participants from being either net borrowers or net lenders. However, if we divide both sides of equation (12c) by S , we get equation (12b) for the market portfolio as defined in equations (1) and (2).

4. Mossin (1966) provides a precise statement of the assumptions behind the S-L CAPM. Specifically all that Mossin assumes about covariances is that the covariance matrix is nonsingular (i.e., that no portfolio of risky securities is riskless).

Modeling Asset Price Dynamics

DESSISLAVA A. PACHAMANOVA, PhD

Associate Professor of Operations Research, Babson College

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: The dynamics of asset price processes in discrete time increments are typically described by two kinds of models: trees (lattices) and random walks. Arithmetic, geometric, and mean reverting random walks are examples of the latter type of models. When the time increment used to model the asset price dynamics becomes infinitely small, we talk about stochastic processes in continuous time. Models for asset price dynamics can incorporate different observed characteristics of an asset price process, such as a drift or a reversion to a mean, and are important building blocks for risk management and financial derivative pricing models.

Many classical asset pricing models, such as the capital asset pricing theory and the arbitrage pricing theory, take a myopic view of investing: They consider events that happen one time period ahead, where the length of the time period is determined by the investor. This entry presents apparatus that can handle asset dynamics and volatility over time. The dynamics of price processes in discrete time increments are typically described by two kinds of models: *trees* (such as *binomial trees*) and *random walks*. When the time increment used to model the asset price dynamics becomes infinitely small, we talk about *stochastic processes* in continuous time.

In this entry, we introduce the fundamentals of binomial tree and random walk models, providing examples for how they can be used in practice. We briefly discuss the special nota-

tion and terminology associated with stochastic processes at the end of the entry; however, our focus is on interpretation and simulation of processes in discrete time. The roots for the techniques we describe are in physics and the other natural sciences. They were first applied in finance at the beginning of the 20th century and have represented the foundations of asset pricing ever since.

FINANCIAL TIME SERIES

Let us first introduce some definitions and notation. A financial time series is a sequence of observations of the values of a financial variable, such as an asset price (index level) or asset (index) returns, over time. Figure 1 shows an example of a time series, consisting of weekly observations of the S&P 500 price level over a

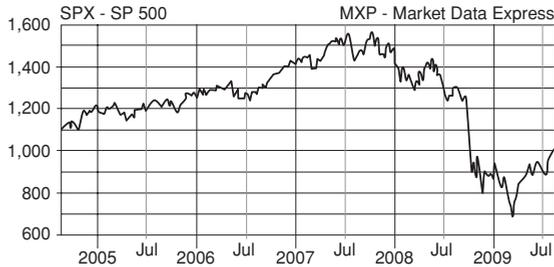

Figure 1 S&P 500 Index Level between August 19, 2005 and August 19, 2009

period of five years (August 19, 2005 to August 19, 2009).

When we describe a time series, we talk about its drift and volatility. The term “drift” is used to indicate the direction of any observable trend in the time series. In the example shown in Figure 1, it appears that the S&P 500 time series has a positive drift up from August 2005 until about the middle of 2007, as the level of prices appears to have been generally increasing over that time period. From the middle of 2007 until the beginning of 2009, there is a negative drift. The volatility is smaller (the time series is less “squiggly”) from August 2005 until about the middle of 2007, but increases dramatically between the middle of 2007 and the beginning of 2009.

We are usually interested also in whether the volatility increases when the price level increases, decreases when the price level decreases, or remains constant independently of the current price level. In this example, the volatility is lower when the price level is increasing, and is higher when the price level is decreasing.

Finally, we talk about the *continuity* of the time series—is the time series smooth, or are there jumps whose magnitude appears to be large relative to the price movements the rest of the time? From August 2005 until about the middle of 2007, the time series is quite smooth. However, some dramatic drops in price levels can be observed between the middle of 2007 and the beginning of 2009—notably in the fall of 2008.

For the remainder of this entry, we will use the following notation:

- S_t : value of underlying variable (price, interest rate, index level, etc.) at time t .
- S_{t+1} : value of underlying variable (price, interest rate, etc.) at time $t + 1$.
- ω_t : a random error term observed at time t . (For the applications in this entry, it will follow a normal distribution with mean equal to 0 and standard deviation equal to σ .)
- ε_t : a realization of a normal random variable with mean equal to 0 and standard deviation equal to 1 at time t .

BINOMIAL TREES

Binomial trees (also called *binomial lattices*) provide a natural way to model the dynamics of a random process over time. The initial value of the security S_0 (at time 0) is known. The length of a time period, Δt , is specified before the tree is built. (The symbol Δ is often used to denote *difference*. The notation Δt therefore means time difference, i.e., length of one time period.)

The binomial tree model assumes that at the next time period, only two values are possible for the price, that is, the price may go up with probability p or down with probability $(1 - p)$. Usually, these values are represented as multiples of the price at the beginning of the period. The factor u is used for an up movement, and d is used for a down movement. For example, the two prices at the end of the first time period are $u \cdot S_0$ and $d \cdot S_0$. If the tree is recombining, there will be three possible prices at the end of the second time period: $u^2 \cdot S_0$, $u \cdot d \cdot S_0$, and $d^2 \cdot S_0$. Proceeding in a similar manner, we can build the tree in Figure 2.

The binomial tree model may appear simple, because, given a current price, it only allows for two possibilities for the price at each time period. However, if the length of the time period is small, it is possible to represent a wide range of values for the price after only a few

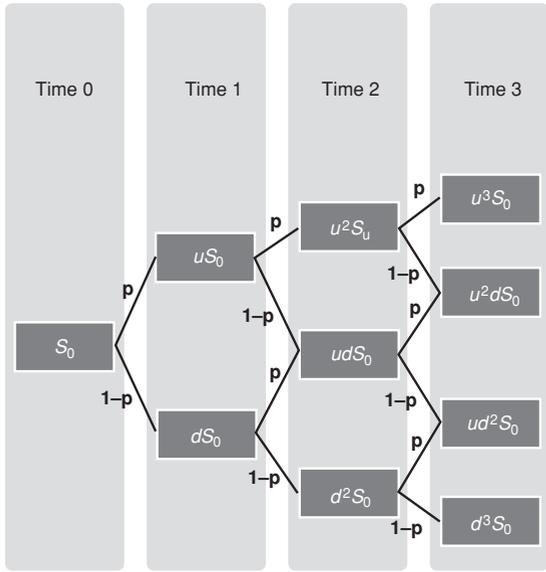

Figure 2 Example of a Binomial Tree

steps. To see this, notice that each step in the tree can be thought of as a Bernoulli trial—it is a “success” with probability p and a “failure” with probability $(1 - p)$. (One can think of the Bernoulli random variable as the numerical coding of the outcome of a coin toss, where one outcome is considered a “success” and one outcome is considered a “failure.” The Bernoulli random variable takes the value 1 (“success”) with probability p and the value of 0 (“failure”) with probability $1 - p$. Note that the definition of success and failure here is arbitrary, because

an increase in price is not always desirable, but we define them in this way for the example’s sake.)

After n steps, each particular value for the price will be reached by realizing k successes and $(n - k)$ failures, where k is a number between 0 and n . The probability of reaching each value for the price after n steps will be

$$P(k \text{ successes}) = \frac{n!}{k!(n - k)!} p^k (1 - p)^{n-k}$$

For large values of n , the shape of the binomial distribution becomes more and more symmetric and looks like a continuum. (See Figure 3(A)–(C).) In fact, the binomial distribution approximates a normal distribution with specific mean and standard deviation related to the probability of success and the number of trials. (The normal distribution is a continuous probability distribution. It is represented by a bell-shaped curve, and the shape of the curve is entirely described by the distribution mean and variance. Figure 4 shows a graph of the standard normal distribution, which has a mean of zero and a standard deviation of 1.) One can therefore represent a large range of values for the price as long as the number of time periods used in the binomial tree is large. Practitioners often use also trinomial trees, that is, trees with three branches emanating from each node, in order to obtain a better representation of the range of possible prices in the future.

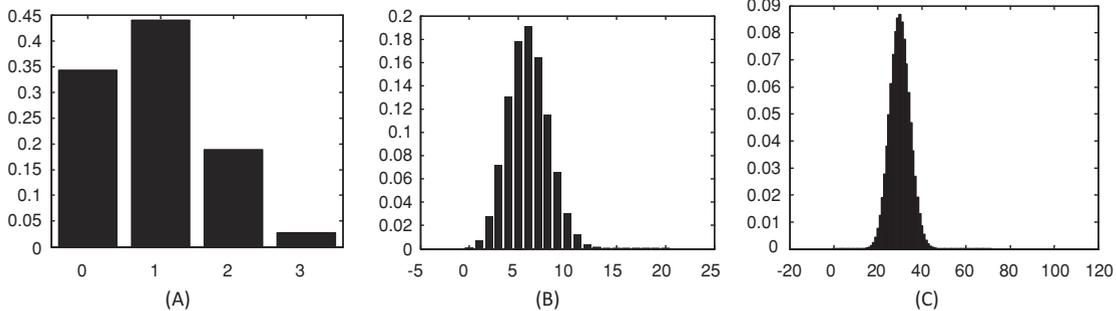

Figure 3 Binomial Distribution

Note: Probability of success (p) assumed to be 0.3. Number of trials (A) $n = 3$; (B) $n = 20$; (C) $n = 100$.

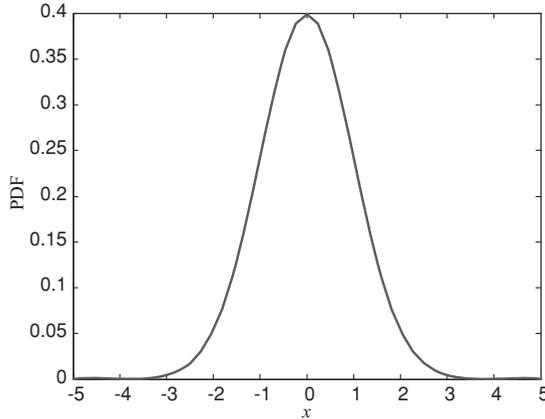

Figure 4 Standard Normal Distribution

ARITHMETIC RANDOM WALKS

Instead of assuming that at each step the asset price can only move up or down by a certain multiple with a given probability, we could assume that the price moves by an amount that follows a normal distribution with mean μ and standard deviation σ . In other words, the price for each period is determined from the price of the previous period by the equation

$$S_{t+1} = S_t + \mu + \tilde{\omega}_t$$

where $\tilde{\omega}_t$ is a normal random variable with mean 0 and standard deviation σ . We will also assume that the random variable $\tilde{\omega}_t$ describing the change in the price in one time period is independent of the random variables describing the change in the price in any other time period. (This is known as the Markov property. It implies that past prices are irrelevant for forecasting the future, and only the current value of the price is relevant for predicting the price in the next time period.) A sequence of independent and identically distributed (IID) random variables $\tilde{\omega}_0, \dots, \tilde{\omega}_t, \dots$ with zero mean and finite variance σ^2 is sometimes referred to as *white noise*.

The movement of the price expressed through the equation above is called an *arithmetic random walk with drift*. The drift term, μ , represents the

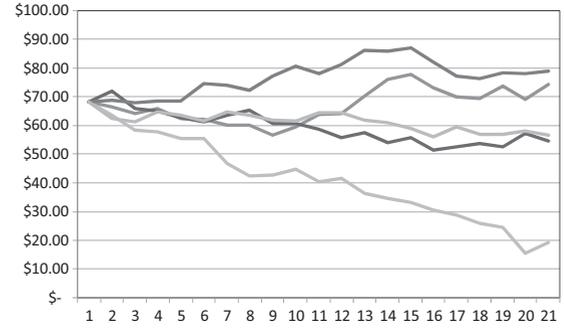

Figure 5 Five Paths of an Arithmetic Random Walk Assuming $\mu = -0.1697$ and $\sigma = 3.1166$

average change in price over a single time period. Note that for every time period t , we can write the equation for the arithmetic random walk as

$$\begin{aligned} S_t &= S_{t-1} + \mu + \tilde{\omega}_{t-1} \\ &= (S_{t-2} + \mu + \tilde{\omega}_{t-2}) + \mu + \tilde{\omega}_{t-1} \\ &= (S_{t-3} + \mu + \tilde{\omega}_{t-3}) + 2 \cdot \mu + \tilde{\omega}_{t-1} + \tilde{\omega}_{t-2} \\ &= S_0 + \mu \cdot t + \sum_{i=0}^{t-1} \tilde{\omega}_i \end{aligned}$$

Therefore, an arithmetic random walk can be thought of as a sum of two terms: a deterministic straight line $S_t = S_0 + \mu \cdot t$ and a sum of all past noise terms. (See Figure 5.)

Simulation

The equation for the arithmetic random walk can be expressed also as

$$S_{t+1} = S_t + \mu + \sigma \cdot \tilde{\varepsilon}_t$$

where $\tilde{\varepsilon}_t$ is a standard normal random variable. To show this, we need to mention that every normal distribution can be expressed in terms of the standard normal distribution, and the latter has mean of 0 and standard deviation of 1. Namely, if $\tilde{\varepsilon}$ is a standard normal variable with mean 0 and standard deviation 1, and \tilde{x} is a normal random variable with mean μ and standard deviation σ , we have

$$\tilde{\varepsilon} = \frac{\tilde{x} - \mu}{\sigma} \text{ (equivalently, } \tilde{x} = \sigma \cdot \tilde{\varepsilon} + \mu \text{)}$$

This is a property unique to the normal distribution—no other family of probability distributions can be transformed in the same way. In the context of the equation for the arithmetic random walk, we have a normal random variable $\tilde{\omega}_t$ with mean 0 and standard deviation σ . It can be expressed through a standard normal variable $\tilde{\varepsilon}_t$ as $\sigma \cdot \tilde{\varepsilon}_t + 0$.

The equation for S_{t+1} above makes it easy to generate paths for the arithmetic random walk by simulation. All we need is a way of generating the standard normal random variables $\tilde{\varepsilon}_t$. We start with an initial price S_0 , which is known. We also know the values of the drift μ and the volatility σ over one period. To generate the price at the next time period, S_1 , we add μ to S_0 , simulate a normal random variable from a standard normal distribution, multiply it by σ , and add it to $S_0 + \mu$. At the next step (time period 2), we use the price at time period 1 we already generated, S_1 , add to it μ , simulate a new random variable from a standard normal distribution, multiply it by σ , and add it to $S_1 + \mu$. We proceed in the same way until we generate the desired number of steps of the random walk. For example, given a current price S , in Excel the price for the next time period can be generated with the formula

$$S + \mu + \sigma * \text{NORMINV}(\text{RAND}(), 0, 1)$$

Parameter Estimation

In order to simulate paths of the arithmetic random walk, we need estimates of the parameters (μ and σ). We need to assume that these parameters remain constant over the time period of estimation. Note that the equation for the arithmetic random walk can be written as

$$S_{t+1} - S_t = \mu + \sigma \cdot \tilde{\varepsilon}_t$$

Given a historical series of T prices for an asset, we can therefore do the following to estimate μ and σ :

1. Compute the price changes $S_{t+1} - S_t$ for each time period t , $t = 0, \dots, T-1$.

2. Estimate the drift of the arithmetic random walk, μ , as the average of all the price changes.
3. Estimate the volatility of the arithmetic random walk, σ , as the standard deviation of all the price changes.

An important point to keep in mind is the units in which the parameters are estimated. If we are given time series in monthly increments, then the estimates of μ and σ we will obtain through steps 1–3 will be for monthly drift and monthly volatility. If we then need to simulate future paths for monthly observations, we can use the same μ and σ . However, if, for example, we need to simulate weekly observations, we will need to adjust μ and σ to account for the difference in the length of the time period. In general, the parameters should be stated as annual estimates. The annual estimates can then be adjusted for daily, weekly, monthly, and so on increments.

For example, suppose that we have estimated the weekly drift and the weekly volatility. To convert the weekly drift to an annual drift, we multiply the number we found for the weekly drift by 52, the number of weeks in a year. To convert the weekly volatility to annual volatility, we multiply the number we found for the weekly volatility by the square root of the number of weeks in a year, that is, by $\sqrt{52}$. Conversely, if we are given annualized values for the drift and the volatility, we can obtain weekly values by dividing the annual drift and the volatility by 52 and $\sqrt{52}$, respectively.

Arithmetic Random Walks: Some Additional Facts

If we use the arithmetic random walk model, any price in the future, S_t , can be expressed through the initial (known) price S_0 as

$$S_t = S_0 + \mu \cdot t + \sigma \cdot \sum_{i=0}^{t-1} \tilde{\varepsilon}_i$$

The random variable corresponding to the sum of t independent normal random variables $\tilde{\varepsilon}_0, \dots, \tilde{\varepsilon}_{t-1}$ is a normal random variable with mean equal to the sum of the means and standard deviation equal to the square root of the sum of variances. Since $\tilde{\varepsilon}_0, \dots, \tilde{\varepsilon}_{t-1}$ are independent standard normal variables, their sum is a normal variable with mean 0 and standard deviation equal to

$$\underbrace{\sqrt{1 + \dots + 1}}_{t \text{ times}} = \sqrt{t}$$

Therefore, we can have a closed-form expression for computing the asset price at time t given the asset price at time 0:

$$S_t = S_0 + \mu \cdot t + \sigma \cdot \sqrt{t} \cdot \tilde{\varepsilon}$$

where $\tilde{\varepsilon}$ is a standard normal random variable.

Based on the discussion so far in this section, we can state the following observations about the arithmetic random walk:

- The arithmetic random walk has a constant drift μ and volatility σ , that is, at every time period, the change in price is normally distributed, on average equal to μ , with a standard deviation of σ .
- The overall noise in a random walk never decays. The price change over t time periods is distributed as a normal distribution with mean equal to $\mu \cdot t$ and standard deviation equal to $\sigma \sqrt{t}$. That is why in industry one often encounters the phrase “The uncertainty grows with the square root of time.”
- Prices that follow an arithmetic random walk meander around a straight line $S_t = S_0 + \mu \cdot t$. They may depart from the line, and then cross it again.
- Because the distribution of future prices is normal, we can theoretically find the probability that the future price at any time will be within a given range.
- Because the distribution of future prices is normal, future prices can theoretically take infinitely large or infinitely small values. Thus, they can be negative, which is an undesirable consequence of using the model.

Asset prices, of course, cannot be negative. In practice, the probability of the price becoming negative can be made quite small as long as the drift and the volatility parameters are selected carefully. However, the possibility of generating negative prices with the arithmetic random walk model is real.

Another problem with the assumptions underlying the arithmetic random walk is that the change in the asset price is drawn from the same random probability distribution, independently of the current level of the prices. A more natural model is to assume that the parameters of the random probability distribution for the change in the asset price vary depending on the current price level. For example, a \$1 change in a stock price is more likely when the stock price is \$100 than when it is \$4. Empirical studies confirm that over time, asset prices tend to grow, and so do fluctuations. Only returns appear to remain stationary, that is, to follow the same probability distribution over time. A more realistic model for asset prices may therefore be that *returns* are an IID sequence. We describe such a model in the next section.

GEOMETRIC RANDOM WALKS

Consider the following model:

$$r_t = \mu + \sigma \cdot \tilde{\varepsilon}_t$$

where $\tilde{\varepsilon}_0, \dots, \tilde{\varepsilon}_t$ is a sequence of independent normal variables, and r_t , the return, is computed as

$$r_t = \frac{S_{t+1} - S_t}{S_t}$$

Returns are therefore normally distributed, and the return over each interval of length 1 has mean μ and standard deviation σ . How can we express future prices if returns are determined by the equations above?

Suppose we know the price at time t , S_t . The price at time $t+1$ can be written as

$$\begin{aligned} S_{t+1} &= S_t \cdot \frac{S_{t+1}}{S_t} \\ &= S_t \cdot \left(\frac{S_t}{S_t} + \frac{S_{t+1} - S_t}{S_t} \right) \\ &= S_t \cdot \left(1 + \frac{S_{t+1} - S_t}{S_t} \right) \\ &= S_t \cdot (1 + \tilde{r}_t) \\ &= S_t + \mu \cdot S_t + \sigma \cdot S_t \cdot \tilde{\varepsilon}_t \end{aligned}$$

This last equation is very similar to the equation for the arithmetic random walk, except that the price from the previous time period appears as a factor in all of the terms.

The equation for the *geometric random walk* makes it clear how paths for the geometric random walk can be generated. As in the case of the arithmetic random walk, all we need is a way of generating the normal random variables $\tilde{\varepsilon}_t$. We start with an initial price S_0 , which is known. We also know the values of the drift μ and the volatility σ over one period. To generate the price at the next time period, S_1 , we add $\mu \cdot S_0$ to S_0 , simulate a normal random variable from a standard normal distribution, multiply it by σ and S_0 , and add it to $S_0 + \mu \cdot S_0$. At the next step (time period 2), we use the price at time period 1 we already generated, S_1 , add to it $\mu \cdot S_1$, simulate a new random variable from a standard normal distribution, multiply it by σ and S_1 , and add it to $S_1 + \mu \cdot S_1$. We proceed in the same way until we generate the desired number of steps of the geometric random walk. For example, given a current price S , in Excel the price for the next time period can be generated with the formula

$$S + \mu * S + \sigma * S * \text{NORMINV}(\text{RAND}(), 0, 1)$$

Using similar logic to the derivation of the price equation earlier, we can express the price at any time t in terms of the known initial price S_0 . Note that we can write the price at time t as

$$S_t = S_0 \cdot \frac{S_1}{S_0} \cdot \dots \cdot \frac{S_{t-1}}{S_{t-2}} \cdot \frac{S_t}{S_{t-1}}$$

Therefore,

$$S_t = S_0 \cdot (1 + \tilde{r}_0) \cdot \dots \cdot (1 + \tilde{r}_{t-1})$$

In the case of the arithmetic random walk, we determined that the price at any time period follows a normal distribution. This was because if we know the starting price S_0 , the price at any time period could be obtained by adding a sum of independent normal random variables to a constant term and S_0 . The sum of independent normal random variables is a normal random variable itself. In the equation for the geometric random walk, each of the terms $(1 + \tilde{r}_0), \dots, (1 + \tilde{r}_{t-1})$ is a normal random variable as well. (It is the sum of a normal random variable and a constant.) However, they are multiplied together. The product of normal random variables is not a normal random variable, which means that we cannot have a nice closed-form expression for computing the price S_t based on S_0 .

To avoid this problem, let us consider the natural logarithm of prices. (The natural logarithm is the function \ln so that $e^{\ln(x)} = x$, where e is the number 2.7182...) Unless otherwise specified, we will use "logarithm" to refer to the natural logarithm, that is, the logarithm of base e .

If we take logarithms of both sides of the equation for S_t , we get

$$\begin{aligned} \ln(S_t) &= \ln(S_0 \cdot (1 + \tilde{r}_0) \cdot \dots \cdot (1 + \tilde{r}_{t-1})) \\ &= \ln(S_0) + \ln(1 + \tilde{r}_0) + \dots + \ln(1 + \tilde{r}_{t-1}) \end{aligned}$$

Log returns are in fact differences of log prices. To see this, note that

$$\begin{aligned} \ln(1 + r_t) &= \ln\left(1 + \frac{S_{t+1} - S_t}{S_t}\right) \\ &= \ln\left(\frac{S_{t+1}}{S_t}\right) \\ &= \ln(S_{t+1}) - \ln(S_t) \end{aligned}$$

Now assume that log returns (not returns) are independent and follow a normal distribution with mean μ and standard deviation σ :

$$\ln(1 + \tilde{r}_t) = \ln(S_{t+1}) - \ln(S_t) = \mu + \sigma \cdot \tilde{\varepsilon}_t$$

As a sum of independent normal variables, the expression

$$\ln(S_0) + \ln(1 + \tilde{r}_0) + \dots + \ln(1 + \tilde{r}_{t-1})$$

is also normally distributed. This means that $\ln(S_t)$ (rather than S_t) is normally distributed, that is, S_t is a lognormal random variable. Similarly to the case of an arithmetic random walk, we can compute a closed-form expression for the price S_t given S_0 :

$$\ln(S_t) = \ln(S_0) + \left(\mu - \frac{1}{2} \cdot \sigma^2 \right) \cdot t + \sigma \cdot \sqrt{t} \cdot \tilde{\varepsilon}$$

or, equivalently,

$$S_t = S_0 \cdot e^{(\mu - \frac{1}{2} \cdot \sigma^2) \cdot t + \sigma \cdot \sqrt{t} \cdot \tilde{\varepsilon}}$$

where $\tilde{\varepsilon}$ is a standard normal variable.

Notice that the only inconsistency with the formula for the arithmetic random walk is the presence of the extra term

$$\left(-\frac{1}{2} \cdot \sigma^2 \right) \cdot t$$

in the drift term

$$\left(\mu - \frac{1}{2} \cdot \sigma^2 \right) \cdot t$$

Why is there an adjustment of one half of the variance in the expected drift? In general, if \tilde{Y} is a normal random variable with mean μ and variance σ^2 , then the random variable, which is an exponential of the normal random variable \tilde{Y} , $\tilde{X} = e^{\tilde{Y}}$, has mean

$$E[\tilde{X}] = e^{\mu + \frac{1}{2} \cdot \sigma^2}$$

At first, this seems unintuitive—why is the expected value of \tilde{X} not

$$E[\tilde{X}] = e^{\mu}?$$

The expected value of a linear function of a random variable is a linear function of the expected value of the random variable. For example, if a is a constant, then

$$E[a \cdot \tilde{Y}] = a \cdot E[\tilde{Y}]$$

However, determining the expected value of a nonlinear function of a random variable (in par-

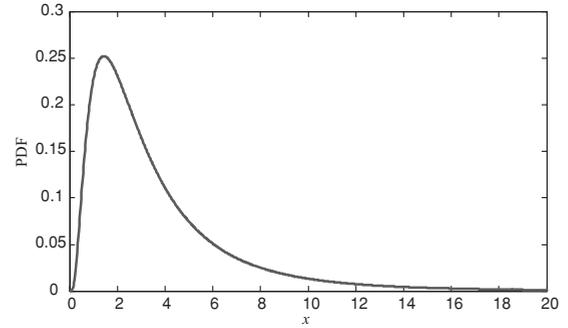

Figure 6 Example of a Lognormal Distribution with Mean of 1 and Standard Deviation of 0.8

ticular, the exponential function, which is the function we are using here) is not as trivial. For example, there is a well-known relationship, the Jensen inequality, which states that the expected value of a convex function of a random variable is less than the value of the function at the expected value of the random variable.

In our example, \tilde{X} is a lognormal random variable, so its probability distribution has the shape shown in Figure 6. The random variable \tilde{X} cannot take values less than 0. Since its variance is related to the variance of the normal random variable \tilde{Y} , as the variance σ^2 of \tilde{Y} increases, the distribution of \tilde{X} will spread out in the upward direction. This means that the mean of the lognormal variable \tilde{X} will increase not only as the mean of the normal variable \tilde{Y} , μ , increases, but also as \tilde{Y} 's variance, σ^2 , increases. In the context of the geometric random walk, \tilde{Y} represents the normally distributed log returns, and \tilde{X} is in fact the factor by which the asset price from the previous period is multiplied in order to generate the asset price in the next time period. In order to make sure that the geometric random process grows exponentially at average rate μ , we need to subtract a term (that term turns out to be $\sigma^2/2$), which will correct the bias.

Specifically, suppose that we know the price at time t , S_t . We have

$$\ln(S_{t+1}) = \ln(S_t) + \ln(1 + \tilde{r}_t)$$

that is,

$$S_{t+1} = S_t \cdot e^{\ln(1+\tilde{r}_t)}$$

Note that we are explicitly assuming a *multiplicative model* for asset prices here—the price in the next time period is obtained by multiplying the price from the previous time period by a random factor. In the case of an arithmetic random walk, we had an additive model—a random shock was added to the asset price from the previous time period.

If the log return $\ln(1 + \tilde{r}_t)$ is normally distributed with mean μ and standard deviation σ , then the expected value of

$$e^{\ln(1+\tilde{r}_t)}$$

is

$$e^{\mu + \frac{1}{2} \cdot \sigma^2}$$

and hence

$$E[S_{t+1}] = S_t \cdot e^{\mu + \frac{1}{2} \cdot \sigma^2}$$

In order to make sure that the geometric random walk process grows exponentially at an average rate μ (rather than $(\mu + 0.5 \cdot \sigma^2)$), we need to subtract the term $0.5 \cdot \sigma^2$ when we generate the future price from this process. This argument can be extended to determining prices for more than one time period ahead.

We will understand better why this formula holds when we review stochastic processes at the end of this entry.

Simulation

It is easy to see how future prices can be generated based on the initial price S_0 . First, we compute the term in the power of e : We simulate a value for a standard normal random variable, multiply it by the standard deviation and the square root of the number of time periods between the initial point and the point we are trying to compute, and subtract the product from the drift term adjusted for the volatility and the number of time periods. We then raise e to the exponent we just computed and multiply

the resulting value by the value of the initial price. For example, given a current price S , in Excel we use the formula

$$S * \exp((\mu - 0.5 * \sigma^2) * t - \sigma * \sqrt{t}) * \text{NORMINV}(\text{RAND}(), 0, 1)$$

One might wonder whether this approach for simulating realizations of an asset price following a geometric random walk is equivalent to the simulation approach mentioned earlier when we introduced geometric random walks, which is based on the discrete version of the equation for a random walk. The two approaches are different (for example, the approach based on the discrete version of the equation for the geometric random walk does not produce the expected lognormal price distribution), but it can be shown that the differences in the two simulation approaches tend to cancel over many steps.

Parameter Estimation

In order to simulate paths of the geometric random walk, we need to have estimates of the parameters (μ and σ). The implicit assumption here, of course, is that these parameters remain constant over the time period of estimation. (We will discuss how to incorporate considerations for changes in volatility later in this entry.) Note that the equation for the geometric random walk can be written as

$$\ln(S_{t+1}) - \ln(S_t) = \ln(1 + \tilde{r}_t)$$

Equivalently,

$$\ln\left(\frac{S_{t+1}}{S_t}\right) = \mu + \sigma \cdot \tilde{\epsilon}_t$$

Given a historical series of T prices of an asset, we can therefore do the following to estimate μ and σ :

1. Compute $\ln(S_{t+1}/S_t)$ for each time period t , $t = 0, \dots, T-1$.
2. Estimate the volatility of the geometric random walk, σ , as the standard deviation of all $\ln(S_{t+1}/S_t)$.

- Estimate for the drift of the arithmetic random walk, μ , as the average of all $\ln(S_{t+1}/S_t)$, plus one half of the standard deviation squared.

If we are given data on the returns r_t of an asset rather than the prices of the asset, we can compute $\ln(1 + r_t)$, and use it to replace $\ln(S_{t+1}/S_t)$ in steps 1–3 above. This is because

$$\log\left(\frac{S_{t+1}}{S_t}\right) = \log\left(1 + \frac{S_{t+1} - S_t}{S_t}\right) = \log(1 + \tilde{r}_t)$$

Geometric Random Walk: Some Additional Facts

To summarize, the geometric random walk has several important characteristics:

- It is a multiplicative model, that is, the price at the next time period is a multiple of a random term and the price from the previous time period.
- It has a constant drift μ and volatility σ . At every time period, the percentage change in price is normally distributed, on average equal to μ , with a standard deviation of σ .
- The overall noise in a geometric random walk never decays. The percentage price change over t time periods is distributed as a normal distribution with mean equal to $\mu \cdot t$ and standard deviation equal to $\sigma \sqrt{t}$.
- The exact distribution of the future price knowing the initial price can be found. The price at time t is lognormally distributed with specific probability distribution parameters.
- Prices that follow a geometric random walk in continuous time never become negative.

The geometric random walk model is not perfect. However, its computational simplicity makes the geometric random walk and its variations the most widely used processes for modeling asset prices. The geometric random walk defined with log returns never becomes negative, because future prices are always a multiple of the initial stock price and a positive term. (See

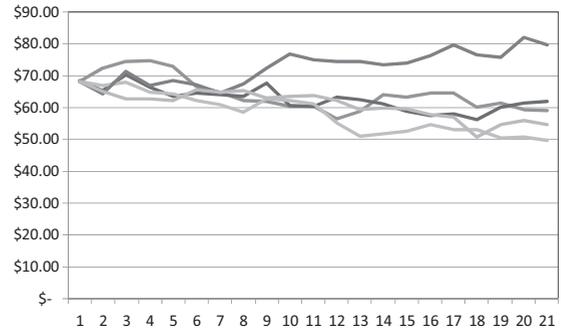

Figure 7 Five Paths of a Geometric Random Walk with $\mu = -0.0014$ and $\sigma = 0.0411$

Note: Although the drift is slightly negative, it is still possible to generate paths that generally increase over time.

Figure 7.) In addition, observed historical stock prices can actually be quite close to lognormal.

It is important to note that, actually, the assumption that log returns are normal is not required to justify the lognormal model for prices. If the distribution of log returns is non-normal, but the log returns are IID with finite variance, the sum of the log returns is asymptotically normal. (This is based on a version of the central limit theorem.) Stated differently, the log return process is approximately normal if we consider changes over sufficiently long intervals of time.

Price processes, however, are not always geometric random walks, even asymptotically. A very important assumption for the geometric random walk is that price increments are independently distributed; if the time series exhibits autocorrelation, the geometric random walk is not a good representation. We will see some models that incorporate considerations for autocorrelation and other factors later in this entry.

MEAN REVERSION

The geometric random walk provides the foundation for modeling the dynamics for asset prices of many different securities, including stock prices. However, in some cases it is not

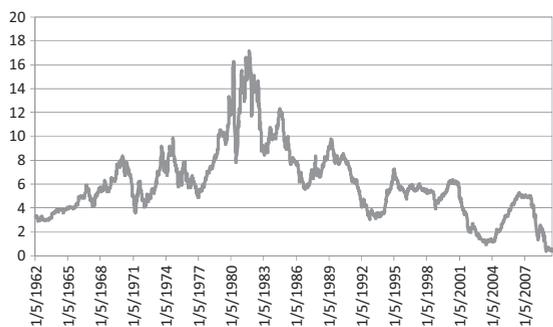

Figure 8 Weekly Data for One-Year Treasury Bill Rates: January 5, 1962–July 31, 2009

justified to assume that asset prices evolve with a particular drift, or can deviate arbitrarily far from some kind of a representative value. Interest rates, exchange rates, and the prices of some commodities are examples for which the geometric random walk does not provide a good representation over the long term. For instance, if the price of copper becomes high, copper mines would increase production in order to maximize profits. This would increase the supply of copper in the market, therefore decreasing the price of copper back to some equilibrium level. Consumer demand plays a role as well—if the price of copper becomes too high, consumers may look for substitutes, which would reduce the price of copper back to its equilibrium level.

Figure 8 illustrates the behavior of the one-year Treasury bill yield from the beginning of January 1962 through the end of July 2009. It can be observed that, even though the variability of Treasury bill rates has changed over time, there is some kind of a long-term average level of interest rates to which they return after deviating up or down. This behavior is known as *mean reversion*.

The simplest mean reversion (MR) model is similar to an arithmetic random walk, but the means of the increments change depending on the current price level. The price dynamics are represented by the equation

$$S_{t+1} = S_t + \kappa \cdot (\mu - S_t) + \sigma \cdot \tilde{\varepsilon}_t$$

where $\tilde{\varepsilon}_t$ is a standard normal random variable. The parameter κ is a nonnegative number that represents the speed of adjustment of the mean-reverting process—the larger its magnitude, the faster the process returns to its long-term mean. The parameter μ is the long-term mean of the process. When the current price S_t is lower than the long-term mean μ , the term $(\mu - S_t)$ is positive. Hence, on average there will be an upward adjustment to obtain the value of the price in the next time period, S_{t+1} . (We add a positive number, $\kappa \cdot (\mu - S_t)$, to the current price S_t .) By contrast, if the current price S_t is higher than the long-term mean μ , the term $(\mu - S_t)$ is negative. Hence, on average there will be a downward adjustment to obtain the value of the price in the next time period, S_{t+1} . (We add a negative number, $\kappa \cdot (\mu - S_t)$, to the current price S_t .) Thus, the mean-reverting process will behave in the way we desire—if the price becomes lower or higher than the long-term mean, it will be drawn back to the long-term mean.

In the case of the arithmetic and the geometric random walks, the cumulative volatility of the process increases over time. By contrast, in the case of mean reversion, as the number of steps increases, the variance peaks at

$$\frac{\sigma^2}{\kappa \cdot (2 - \kappa)}$$

In continuous time, this basic mean-reversion process is called the *Ornstein-Uhlenbeck process*. (See the last section of this entry.) It is widely used when modeling interest rates and exchange rates in the context of computing bond prices and prices of more complex fixed-income securities. When used in the context of modeling interest rates, this simple mean-reversion process is also referred to as the Vasicek model (see Vasicek, 1977).

The mean-reversion process suffers from some of the disadvantages of the arithmetic random walk—for example, it can technically become negative. However, if the long-run mean is positive, and the speed of mean reversion is large relative to the volatility, the price will be

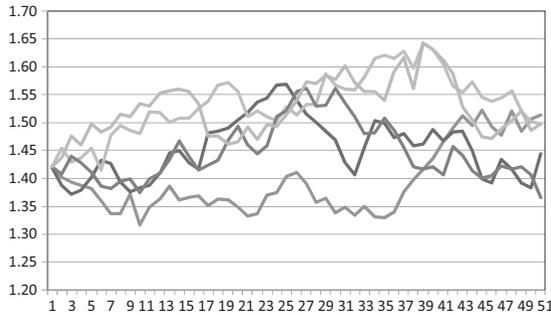

Figure 9 Five Paths with 50 Steps Each of a Mean-Reverting Process with $\mu = 1.4404$, $\kappa = 0.0347$, and $\sigma = 0.0248$

pulled back to the mean quickly when it becomes negative. Figure 9 contains an example of five paths generated from a mean-reverting process.

Simulation

The formula for the mean-reverting process makes it clear how paths for the mean-reverting random walk can be generated. As in the case of the arithmetic and the geometric random walks, all we need is a way of simulating the standard normal random variables $\tilde{\epsilon}_t$. We start with an initial price S_0 , which is known. We know the values of the drift μ , the speed of adjustment κ , and the volatility σ over one period. To generate the price at the next time period, S_1 , we add $\kappa \cdot (\mu - S_0)$ to S_0 , simulate a normal random variable from a standard normal distribution, multiply it by σ , and add it to $S_0 + \kappa \cdot (\mu - S_0)$. At the next step (time period 2), we use the price at time period 1 we already generated, S_1 , add to it $\kappa \cdot (\mu - S_1)$, simulate a new random variable from a standard normal distribution, multiply it by σ , and add it to $S_1 + \kappa \cdot (\mu - S_1)$. We proceed in the same way until we generate the desired number of steps of the random walk. For example, given a current price S , in Excel the price for the next time period can be generated with the formula

$$S + \kappa \cdot (\mu - S) + \sigma \cdot \text{NORMINV}(\text{RAND}(), 0, 1)$$

Parameter Estimation

In order to simulate paths of the mean-reverting random walk, we need estimates of the parameters (κ , μ , and σ). Again, we assume that these parameters remain constant over the time period of estimation. The equation for the mean-reverting process can be written as

$$S_{t+1} - S_t = \kappa \cdot (\mu - S_t) + \sigma \cdot \tilde{\epsilon}_t$$

or, equivalently,

$$S_{t+1} - S_t = \kappa \cdot \mu - \kappa \cdot S_t + \sigma \cdot \tilde{\epsilon}_t$$

This equation has the characteristics of a linear regression model, with the absolute price change ($S_{t+1} - S_t$) as the response variable and S_t as the explanatory variable. Given a historical series of T prices for an asset, we can therefore do the following to estimate κ , μ , and σ :

1. Compute the price changes ($S_{t+1} - S_t$) for each time period t , $t = 0, \dots, T-1$.
2. Run a linear regression with ($S_{t+1} - S_t$) as the response variable and S_t as the explanatory variable.
3. Verify that the estimates from the linear regression model are valid:
 - a. Plot the values of S_t versus ($S_{t+1} - S_t$). The points in the scatter plot should approximately vary around a straight line with no visible cyclical or other patterns.
 - b. The p -value for the coefficient in front of the explanatory variable S_t should be small, preferably less than 0.05. (The p -values of the regression coefficients are part of standard regression output for most software packages. Most generally, they measure the degree of significance of the regression coefficient for explaining the response variable in the regression.)
4. An estimate for the speed of adjustment of the mean-reversion process, κ , can be obtained as the negative of the coefficient in front of S_t . Since the speed of adjustment cannot be a negative number, if the coefficient in front of S_t is positive, the regression model

cannot be used for estimating the parameters of the mean reverting process.

5. An estimate for the long-term mean of the mean-reverting process, μ , can be obtained as the ratio of the intercept term estimated from the regression and the slope coefficient in front of S_t (if that slope coefficient is valid, i.e., negative and with low p -value).
6. An estimate for the volatility of the mean-reverting process, σ , can be obtained as the standard error of the regression. (The standard error of the regression is also part of standard regression output for statistical software packages and spreadsheet programs like Excel. It measures the standard deviation of the points around the regression line.)

Geometric Mean Reversion

A more advanced mean-reversion model that bears some similarity to the geometric random walk is the geometric mean reversion (GMR) model

$$S_{t+1} = S_t + \kappa \cdot (\mu - S_t) \cdot S_t + \sigma \cdot S_t \cdot \tilde{\epsilon}_t$$

(Note that this is a special case of the mean reversion model $S_{t+1} = S_t + \kappa \cdot (\mu - S_t) \cdot S_t + \sigma \cdot S_t^\gamma \cdot \tilde{\epsilon}_t$, where γ is a parameter selected in advance. The most commonly used models have $\gamma = 1$ or $\gamma = 1/2$.) The intuition behind this model is similar to the intuition behind the discrete version of the geometric random walk—the variability of the process changes with the current level of the price. However, the GMR model allows for incorporating mean reversion. Even though it is difficult to estimate the future price analytically from this model, it is easy to simulate. For example, given a current price S , in Excel the price for the next time period can be generated with the formula

$$S + \kappa * (\mu - S) * S + \sigma * S$$

*NORMINV(RAND(), 0, 1)

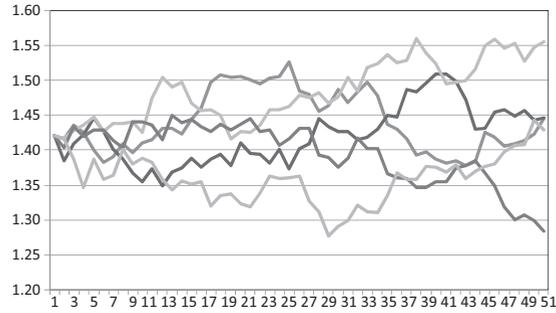

Figure 10 Five Paths with 50 Steps Each of a Geometric Mean Reversion Process with $\mu = 1.4464$, $\kappa = 0.0253$, and $\sigma = 0.0177$

Figure 10 contains an example of five paths generated from a geometric mean reversion model.

To estimate the parameters κ , μ , and σ to use in the simulation, we can use a series of T historical observations for the price of an asset. Assume that the parameters of the geometric mean reversion remain constant during the time period of estimation.

Note that the equation for the geometric mean-reverting random walk can be written as

$$\frac{S_{t+1} - S_t}{S_t} = \kappa \cdot (\mu - S_t) + \sigma \cdot \tilde{\epsilon}_t$$

or, equivalently, as

$$\frac{S_{t+1} - S_t}{S_t} = \kappa \cdot \mu - \kappa \cdot S_t + \sigma \cdot \tilde{\epsilon}_t$$

Again, this equation bears characteristics of a linear regression model, with the percentage price change $(S_{t+1} - S_t)/S_t$ as the response variable and S_t as the explanatory variable. Given a historical series of T prices of an asset, we can therefore do the following to estimate κ , μ , and σ :

1. Compute the percentage price changes $(S_{t+1} - S_t)/S_t$ for each time period t , $t = 0, \dots, T-1$.
2. Run a linear regression with $(S_{t+1} - S_t)/S_t$ as the response variable and S_t as the explanatory variable.

3. Verify that the estimates from the linear regression model are valid:
 - a. Plot the values of S_t versus $(S_{t+1} - S_t)/S_t$. The points in the scatter plot should approximately vary around a straight line with no visible cyclical or other patterns.
 - b. The p -value for the coefficient in front of the explanatory variable S_t should be small, preferably less than 0.05.
4. An estimate for the speed of adjustment of the mean-reverting process, κ , can be obtained as the negative of the coefficient in front of S_t . Since the speed of adjustment cannot be a negative number, if the coefficient in front of S_t is positive, the regression model cannot be used for estimating the parameters of the geometric mean-reverting process.
5. An estimate for the long-term mean of the mean-reverting process, μ , can be obtained as the ratio of the intercept term estimated from the regression and the slope coefficient in front of S_t (if that slope coefficient is valid, i.e., negative and with low p -value).
6. An estimate for the volatility of the mean-reverting process, σ , can be obtained as the standard error of the regression.

ADVANCED RANDOM WALK MODELS

The models we described so far provide building blocks for representing the asset price dynamics. However, observed real-world asset price dynamics has features that cannot be incorporated in these basic models. For example, asset prices exhibit correlation—both with each other and with themselves over time. Their volatility typically cannot be assumed to be constant. This section reviews several techniques for making asset price models more realistic depending on observed price behavior.

Correlated Random Walks

So far, we have discussed models for asset prices that assume that the dynamic processes for the prices of different assets evolve inde-

pendently of each other. This is an unrealistic assumption—it is expected that market conditions and other factors will have an impact on the prices of groups of assets simultaneously. For example, it is likely that stock prices for companies in the oil industry will generally move together, as will stock prices for companies in the telecommunications industry.

The argument that asset prices are codependent has theoretical and empirical foundations as well. If asset prices were independent random walks, then large portfolios would be fully diversified, have no variability, and therefore be completely deterministic. Empirically, this is not the case. Even large aggregates of stock prices, such as the S&P 500, exhibit random behavior.

If we make the assumption that log returns are jointly normally distributed, then their dependencies can be represented through the covariance matrix (equivalently, through the correlation matrix). It is worth noting that in general, covariance and correlation are not equivalent with dependence of random variables. Covariance and correlation measure only the strength of linear dependence between two random variables. However, in the case of a multivariate normal distribution, covariance and correlation are sufficient to represent dependence.

Let us give an example of how one can model two correlated stock prices assumed to follow geometric random walks. Suppose we are given two historical series of T observations each of observed asset prices for Stock 1 and Stock 2. We follow the steps described in the previous sections of this entry to estimate the drifts and the volatilities of the two processes. To estimate the correlation structure, we find the correlation between

$$\ln \left(\frac{S_{t+1}^{(1)}}{S_t^{(1)}} \right) \quad \text{and} \quad \ln \left(\frac{S_{t+1}^{(2)}}{S_t^{(2)}} \right)$$

where the indices (1) and (2) correspond to Stock 1 and Stock 2, respectively. For example, in Excel the correlation between two data series

stored in Array1 and Array2 can be computed with the function CORREL(Array1, Array2). This correlation can then be incorporated in the simulation. (Excel cannot simulate correlated normal random variables. A number of Excel add-ins for simulation are available, however, and they have the capability to do so. Such add-ins include @RISK (sold by Palisade Corporation, <http://www.palisade.com>), Crystal Ball (sold by Oracle, <http://www.oracle.com>), and Risk Solver (from Frontline Systems, the developers of the original Excel Solver, <http://www.solver.com>.) Basically, at every step, we generate correlated normal random variables, $\varepsilon_t^{(1)}$ and $\varepsilon_t^{(2)}$, with means of zero and with a given covariance structure. Those realizations of the correlated normal random variables are then used to compute the next period's Stock 1 price and the next period's Stock 2 price.

When we consider many different assets, the covariance matrix becomes very large and cannot be estimated accurately. Factor models can be used to reduce the dimension of the covariance structure. Multivariate random walks are in fact dynamic factor models for asset prices. A multifactor model for the return of asset i can be written in the following general form:

$$r_t^{(i)} = \mu^{(i)} + \sum_{k=1}^K \beta^{(i,k)} \cdot f_t^{(k)} + \varepsilon_t^{(i)}$$

where the K factors $f^{(k)}$ follow random walks, $\beta^{(i,k)}$ are the factor loadings, and $\varepsilon_t^{(i)}$ are normal random variables with zero means.

It is important to note that the covariance matrix cannot capture correlations at lagged times (i.e., correlations of dynamic nature). Furthermore, the assumptions that log returns behave as multivariate normal variables is not always applicable—some assets exhibit dependency of a nonlinear kind, which cannot be captured by the covariance or correlation matrix. Alternative tools for modeling covariability include copula functions and transfer entropies. (See, for example, Chapter 17 and Appendix B in Fabozzi, Focardi, and Kolm, 2006.)

Incorporating Jumps

Many of the dynamic asset price processes used in industry assume continuous sample paths, as was the case with the arithmetic, geometric, and the different mean-reverting random walks we considered earlier in this entry. However, there is empirical evidence that the prices of many securities incorporate jumps. The prices of some commodities, such as electricity and oil, are notorious for exhibiting “spikes.” The logarithm of a price process with jumps is not normally distributed, but is instead characterized by a high peak and heavy tails, which are more typical of market data than the normal distribution. Thus, more advanced models are needed to incorporate realistic price behavior.

A classical way to include jumps in models for asset price dynamics is to add a Poisson process to the process (geometric random walk or mean reversion) used to model the asset price. A Poisson process is a discrete process in which arrivals occur at random discrete points in time, and the times between arrivals follow an exponential distribution with average time between arrivals equal to $1/\lambda$. This means that the number of arrivals in a specific time interval follows a Poisson distribution with mean rate of arrival λ . The “jump” Poisson process is assumed to be independent of the underlying “smooth” random walk.

The Poisson process is typically used to figure out the times at which the jumps occur. The magnitude of the jumps itself could come from any distribution, although the lognormal distribution is often used for tractability.

Let us explain in more detail how one would model and simulate a geometric random walk with jumps. At every point in time, the process moves as a geometric random walk and updates the price S_t to S_{t+1} . If a jump happens, the size of the jump is added to S_t as well to obtain S_{t+1} . In order to avoid confusion about whether we have included the jump in the calculation, let us denote the price right before we find out whether a jump has occurred $S_{t+1}^{(-)}$, and keep the

total price for the next time period as S_{t+1} . We therefore have

$$S_{t+1}^{(-)} = S_t + \mu \cdot S_t + \sigma \cdot S_t \cdot \tilde{\varepsilon}_t$$

that is, $S_{t+1}^{(-)}$ is computed according to the normal geometric random walk rule. Now suppose that a jump of magnitude \tilde{J}_t occurs between time t and time $t+1$. Let us express the jump magnitude as a percentage of the asset price, that is, let

$$S_{t+1} = S_{t+1}^{(-)} \cdot \tilde{J}_t$$

If we restrict the magnitude of the jumps \tilde{J}_t to be nonnegative, we will make sure that the asset price itself does not become negative.

Let us now express the changes in price in terms of the jump size. Based on the relationship between S_{t+1} , $S_{t+1}^{(-)}$, and \tilde{J}_t , we can write

$$S_{t+1} - S_{t+1}^{(-)} = S_{t+1}^{(-)} \cdot (\tilde{J}_t - 1)$$

and hence

$$S_{t+1}^{(-)} = S_{t+1} - S_{t+1}^{(-)} \cdot (\tilde{J}_t - 1)$$

Thus, we can substitute this expression for $S_{t+1}^{(-)}$ and write the geometric random walk with jumps model as

$$S_{t+1} = S_t + \mu \cdot S_t + \sigma \cdot S_t \cdot \tilde{\varepsilon}_t + S_{t+1}^{(-)} \cdot (\tilde{J}_t - 1)$$

How would we simulate a path for the jump-geometric random walk process? Note that given the relationship between S_{t+1} , $S_{t+1}^{(-)}$, and \tilde{J}_t , we can write

$$\ln(S_{t+1}) = \ln(S_{t+1}^{(-)}) + \ln(\tilde{J}_t)$$

Since $S_{t+1}^{(-)}$ is the price resulting only from the geometric random walk at time t , we already know what $\ln(S_{t+1}^{(-)})$ is. Recall based on our discussion of the geometric random walk that

$$\ln(S_{t+1}^{(-)}) = \ln(S_t) + (\mu - 0.5 \cdot \sigma^2) + \sigma \tilde{\varepsilon}_t$$

Therefore, the overall equation will be

$$\begin{aligned} \ln(S_{t+1}) &= \ln(S_t) + (\mu - 0.5 \cdot \sigma^2) + \sigma \cdot \tilde{\varepsilon}_t \\ &\quad + \sum_i \ln(J_t^{(i)}) \end{aligned}$$

where $J_t^{(i)}$ are all the jumps that occur during the time period between t and $t+1$. This means that

$$S_{t+1} = S_t \cdot e^{\mu - 0.5 \cdot \sigma^2 + \sigma \cdot \tilde{\varepsilon}_t} \cdot \prod_i J_t^{(i)}$$

where the symbol Π denotes product. (If no jumps occurred between t and $t+1$, we set the product to 1.)

Hence, to simulate the price at time $t+1$, we need to simulate

- A standard normal random variable $\tilde{\varepsilon}_t$, as in the case of a geometric random walk.
- How many jumps occur between t and $t+1$.
- The magnitude of each jump.

For more details, see Pachamanova and Fabozzi (2010) and Glasserman (2004).

As Merton (1976) pointed out, if we assume that the jumps follow a lognormal distribution, then $\ln(\tilde{J}_t)$ is normal, and the simulation is even easier. See Glasserman (2004) for more advanced examples.

Stochastic Volatility

The models we considered so far all assumed that the volatility of the stochastic process remains constant over time. Empirical evidence suggests that the volatility changes over time, and more advanced models recognize that fact. Such models assume that the volatility parameter σ itself follows a random walk of some kind. Since there is some evidence that volatility tends to be mean-reverting, often different versions of mean-reversion models are used. For more details on stochastic volatility models and their simulation see, for example, Glasserman (2004) and Hull (2008).

STOCHASTIC PROCESSES

In this section, we provide an introduction to what is known as stochastic calculus. Our goal is not to achieve a working knowledge in the

subject, but rather to provide context for some of the terminology and the formulas encountered in the literature on modeling asset prices with random walks.

So far, we discussed random walks for which every step is taken at a specific discrete point in time. When the time increments are very small, almost zero in length, the equation of a random walk describes a stochastic process in continuous time. In this context, the arithmetic random walk model is known as a *generalized Wiener process* or *Brownian motion* (BM). The geometric random walk is referred to as *geometric Brownian motion* (GBM), and the arithmetic mean-reverting walk is the Ornstein-Uhlenbeck process described earlier.

Special notation is used to denote stochastic processes in continuous time. Increments are denoted by d or Δ . (For example, $(S_{t+1} - S_t)$ is denoted dS_t , meaning a change in S_t over an infinitely small interval.) The equations describing the process, however, have a very similar form to the equations we introduced earlier in this section:

$$dS_t = \mu dt + \sigma dW$$

Equations involving small changes (“differences”) in variables are referred to as *differential equations*. In words, the equation above reads “The change in the price S_t over a small time period dt equals the average drift μ multiplied by the small time change plus a random term equal to the volatility σ multiplied by dW , where dW is the increment of a Wiener process.” The Wiener process, or Brownian motion, is the fundamental building block for many of the classical asset price processes.

A standard Wiener process $W(t)$ has the following properties:

1. For any time $s < t$, the difference $W(t) - W(s)$ is a normal random variable with mean zero and variance $(t - s)$. It can be expressed as $\sqrt{t - s} \cdot \tilde{\epsilon}$, where $\tilde{\epsilon}$ is a standard normal random variable.
2. For any times $0 \leq t_1 < t_2 \leq t_3 < t_4$, the differences $(W(t_2) - W(t_1))$ and $(W(t_4) - W(t_3))$ (which are random variables) are independent. (These differences are the actual increments of the process at different points in time.) Note that independent implies uncorrelated.
3. The value of the Wiener process at the beginning is zero, $W(t_0) = 0$.

Using the new notation, the first two properties can be restated as

Property 1. The change dW during a small period of time dt is normally distributed with mean 0 and variance dt and can be expressed as $\sqrt{dt} \cdot \tilde{\epsilon}$.

Property 2. The values of dW for any two nonoverlapping time intervals are independent.

The arithmetic random walk can be obtained as a *generalized Wiener process*, which has the form

$$dS_t = a dt + b dW$$

The appeal of the generalized Wiener process is that we can find a closed-form expression for the price at any time period. Namely,

$$S_t = S_0 + a \cdot t + b \cdot W(t)$$

The generalized Wiener process is a special case of the more general class of *Ito processes*, in which both the drift term and the coefficient in front of the random term are allowed to be nonconstant. The equation for an Ito process is

$$dS_t = a(S, t) dt + b(S, t) dW$$

GBM and the Ornstein-Uhlenbeck process are both special cases of Ito processes.

In contrast to the generalized Wiener process, the equation for the Ito process does not allow us to write a general expression for the price at time t in closed form. However, an expression can be found for some special cases, such as GBM. We now show how this can be derived.

The main relevant result from stochastic calculus is the so-called Ito’s lemma, which states

the following. Suppose that a variable x follows an Ito process

$$dx_t = a(x, t) dt + b(x, t) dW$$

and let y be a function of x , that is,

$$y_t = f(x, t)$$

Then, y evolves according to the following differential equation:

$$dy_t = \left(\frac{\partial f}{\partial x} \cdot a + \frac{\partial f}{\partial t} + \frac{1}{2} \cdot \frac{\partial^2 f}{\partial x^2} \cdot b^2 \right) dt + \frac{\partial f}{\partial x} \cdot b \cdot dW$$

where the symbol ∂ is standard notation for the partial derivative of the function f with respect to the variable in the denominator. For example, $\partial f / \partial t$ is the derivative of the function f with respect to t assuming that all terms in the expression for f that do not involve t are constant. Respectively, ∂^2 denotes the second derivative of the function f with respect to the variable in the denominator, that is, the derivative of the derivative.

This expression shows that a function of a variable that follows an Ito process also follows an Ito process.

Although a rigorous proof of Ito's lemma is beyond the scope of this entry, we will provide some intuition. Let us see how we would go about computing the expression for y in Ito's lemma.

In ordinary calculus, we could obtain an expression for a function of a variable in terms of that variable by writing the Taylor series extension:

$$dy = \frac{\partial f}{\partial x} \cdot dx + \frac{\partial f}{\partial t} \cdot dt + \frac{1}{2} \cdot \frac{\partial^2 f}{\partial x^2} \cdot dx^2 + \frac{1}{2} \cdot \frac{\partial^2 f}{\partial t^2} \cdot dt^2 + \frac{\partial^2 f}{\partial x \partial t} \cdot dx dt + \dots$$

We will get rid of all terms of order dt^2 or higher, deeming them too small. We need to expand the terms that contain dx , however, because they will contain terms of order dt . We

have

$$dy = \frac{\partial f}{\partial x} \cdot (a(x, t) dt + b(x, t) dW) + \frac{\partial f}{\partial t} \cdot dt + \frac{1}{2} \cdot \frac{\partial^2 f}{\partial x^2} \cdot (a(x, t) dt + b(x, t) dW)^2$$

The last expression in parentheses, when expanded, becomes (dropping the arguments of a and b for notational convenience)

$$(a dt + b dW)^2 = a^2(dt)^2 + b^2(dW)^2 + 2ab \cdot dt \cdot dW = b^2 dt$$

To obtain this expression, we dropped the first and the last term in the expanded expression, because they are of order higher than dt . The middle term, $b^2(dW)^2$, in fact equals $b^2 \cdot dt$ as dt goes to 0. The latter is not an obvious fact, but it follows from the properties of the standard Wiener process. The intuition behind it is that the variance of $(dW)^2$ is of order dt^2 , so we can ignore it and treat the expression as deterministic and equal to its expected value. The expected value of $(dW)^2$ is in fact dt .

Substituting this expression back into the expression for dy , we obtain the expression in Ito's lemma.

Using Ito's lemma, let us derive the equation for the price at time t , S_t that was the basis for the exact simulation method for the geometric random walk. Suppose that S_t follows the GBM

$$dS_t = (\mu \cdot S_t) dt + (\sigma \cdot S_t) dW$$

We will use Ito's lemma to compute the equation for the process followed by the logarithm of the stock price. In other words, in the notation we used in the definition of Ito's lemma, we have

$$y_t = f(x, t) = \ln S_t$$

We also have

$$a = \mu \cdot S \quad \text{and} \quad b = \sigma \cdot S$$

Finally, we have

$$\frac{\partial f}{\partial x} = \frac{\partial(\ln S)}{\partial S} = \frac{1}{S} \quad \text{and} \quad \frac{\partial^2 f}{\partial x^2} = \frac{\partial(1/S)}{\partial S} = -\frac{1}{S^2}$$

Plugging into the equation for y in Ito's lemma, we obtain

$$\begin{aligned} d \ln S &= \left(\frac{1}{S} \cdot a + 0 + \frac{1}{2} \cdot \left(-\frac{1}{S^2} \right) \cdot b^2 \right) dt \\ &\quad + \frac{1}{S} \cdot b \cdot dW \\ &= \left(\mu - \frac{1}{2} \cdot \sigma^2 \right) dt + \sigma \cdot dW \end{aligned}$$

which is the equation we presented earlier. This also explains the presence of the

$$-\frac{1}{2} \cdot \sigma^2$$

term in the expression for the drift of the GBM.

KEY POINTS

- Models of asset dynamics include trees (such as binomial trees) and random walks (such as arithmetic, geometric, and mean-reverting random walks). Such models are called discrete when the changes in the asset price are assumed to happen at discrete time increments. When the length of the time increment is assumed to be infinitely small, we refer to them as stochastic processes in continuous time.
- The arithmetic random walk is an additive model for asset prices—at every time period, the new price is determined by the price at the previous time period plus a deterministic drift term and a random shock that is distributed as a normal random variable with mean equal to zero and a standard deviation proportional to the square root of the length of the time period. The probability distribution of future asset prices conditional on a known current price is normal.
- The arithmetic random walk model is analytically tractable and convenient; however, it has some undesirable features such as a nonzero probability that the asset price will become negative.
- The geometric random walk is a multiplicative model for asset prices—at every time period, the new price is determined by the price at the previous time period multiplied by a deterministic drift term and a random shock that is distributed as a lognormal random variable. The volatility of the process grows with the square root of the elapsed amount of time. The probability distribution of future asset prices conditional on a known current price is lognormal.
- The geometric random walk is not only analytically tractable, but is more realistic than the arithmetic random walk, because the asset price cannot become negative. It is widely used in practice, particularly for modeling stock prices.
- Mean reversion models assume that the asset price will meander, but will tend to return to a long-term mean at a speed called the speed of adjustment. They are particularly useful for modeling prices of some commodities, interest rates, and exchange rates.
- The codependence structure between the price processes for different assets can be incorporated directly (by computing the correlation between the random terms in their random walks), by using dynamic multifactor models, or by more advanced means such as copula functions and transfer entropies.
- A variety of more advanced random walk models are used to incorporate different assumptions, such as time-varying volatility and “spikes,” or jumps, in the asset price. They are not as tractable analytically as the classical random walk models, but can be simulated.
- The Wiener process, a stochastic process in continuous time, is a basic building block for many of the stochastic processes used to model asset prices. The increments of a Wiener process are independent, normally distributed random variables with variance proportional to the length of the time period.
- An Ito process is a generalized Wiener process with drift and volatility terms that can be functions of the asset price and time.

- An important result in stochastic calculus is Ito's lemma, which states that a variable that is a function of a variable that follows an Ito process follows an Ito process itself with specific drift and volatility terms.

Arbitrage Pricing: Finite-State Models

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Arbitrage in its most basic form involves the simultaneous buying and selling of an asset at two different prices in two different markets. In real-world financial markets, arbitrage opportunities rarely, if ever, exist. Less obvious arbitrage opportunities exist in situations where a package of assets can be assembled that have a payoff (return) that is identical to an asset that is priced differently. A market is said to be a complete market if an arbitrary payoff can be replicated by a portfolio. The most fundamental principle in asset pricing theory is the absence of arbitrage opportunities.

The principle of *absence of arbitrage* or the no-arbitrage principle is perhaps the most fundamental principle of finance theory. In the presence of arbitrage opportunities, there is no trade-off between risk and returns because it is possible to make unbounded risk-free gains. The principle of absence of arbitrage is fundamental for understanding asset valuation in a competitive market. This entry discusses arbitrage pricing in a *finite-state*, discrete-time setting. However, it is important to note that there are well-known limits to arbitrage, first identified by Shleifer and Vishny (1997), resulting from restrictions imposed on rational traders and, as a result, pricing inefficiencies may exist for a period of time.

THE ARBITRAGE PRINCIPLE

Let's begin by defining what is meant by arbitrage. In its simple form, *arbitrage* is the

simultaneous buying and selling of an asset at two different prices in two different markets. The arbitrageur profits without risk by buying cheap in one market and simultaneously selling at the higher price in the other market. Such opportunities for arbitrage are rare. In fact, a single arbitrageur with unlimited ability to sell short could correct a mispricing condition by financing purchases in the underpriced market with proceeds from short sales in the overpriced market. This means that riskless arbitrage opportunities are short-lived.

Less obvious arbitrage opportunities exist in situations where a package of assets can produce a payoff (return) identical to an asset that is priced differently. This arbitrage relies on a fundamental principle of finance called the *law of one price*, which states that a given asset must have the same price regardless of the location where the asset is traded and the means by which one goes about creating that asset. The

law of one price implies that if the payoff of an asset can be synthetically created by a package of assets, the price of the package and the price of the asset whose payoff it replicates must be equal.

When a situation is discovered whereby the price of the package of assets differs from that of an asset with the same payoff, rational investors will trade these assets in such a way so as to restore price equilibrium. This market mechanism is founded on the fact that an arbitrage transaction does not expose the investor to any adverse movement in the market price of the assets in the transaction.

For example, consider how we can produce an arbitrage opportunity involving three assets A, B, and C. These assets can be purchased today at the prices shown below, and can each produce only one of two payoffs (referred to as State 1 and State 2) a year from now:

Asset	Price	Payoff in State 1	Payoff in State 2
A	\$70	\$50	\$100
B	60	30	120
C	80	38	112

While it is not obvious from the data presented above, an investor can construct a portfolio of assets A and B that will have the identical payoff as asset C in both State 1 and State 2. Let w_A and w_B be the proportion of assets A and B, respectively, in the portfolio. Then the payoff (i.e., the terminal value of the portfolio) under the two states can be expressed mathematically as follows:

- If State 1 occurs: $\$50 w_A + \$30 w_B$
- If State 2 occurs: $\$100 w_A + \$120 w_B$

We create a portfolio consisting of A and B that will reproduce the payoff of C regardless of the state that occurs one year from now. Here is how: For either condition (State 1 and State 2), we set the payoff of the portfolio equal to the payoff for C as follows:

- State 1: $\$50 w_A + \$30 w_B = \$38$
- State 2: $\$100 w_A + \$120 w_B = \$112$

We also know that $w_A + w_B = 1$. If we solved for the weights for w_A and w_B that would simultaneously satisfy the above equations, we would find that the portfolio should have 40% in asset A (i.e., $w_A = 0.4$) and 60% in asset B (i.e., $w_B = 0.6$). The cost of that portfolio will be equal to

$$(0.4)(\$70) + (0.6)(\$60) = \$64$$

Our portfolio (i.e., package of assets) comprised of assets A and B has the same payoff in State 1 and State 2 as the payoff of asset C. The cost of asset C is \$80 while the cost of the portfolio is only \$64. This is an arbitrage opportunity that can be exploited by buying assets A and B in the proportions given above and shorting (selling) asset C.

For example, suppose that \$1 million is invested to create the portfolio with assets A and B. The \$1 million is obtained by selling short asset C. The proceeds from the short sale of asset C provide the funds to purchase assets A and B. Thus, there would be no cash outlay by the investor. The payoffs for States 1 and 2 are shown below:

Asset	Investment	State 1	State 2
A	\$ 400,000	\$ 285,715	\$ 571,429
B	600,000	300,000	1,200,000
C	-1,000,000	-475,000	-1,400,000
Total	0	\$110,715	\$371,429

ARBITRAGE PRICING IN A ONE-PERIOD SETTING

We can describe the concepts of arbitrage pricing in a more formal mathematical context. It is useful to start in a simple one-period, finite-state setting as in the example of the previous section. This means that we consider only one period and that there is only a finite number M of states of the world. In this setting, asset prices can assume only a finite number of values.

The assumption of finite states is not as restrictive as it might appear. In practice,

security prices can only assume a finite number of values. Stock prices, for example, are not real numbers but integer fractions of a dollar. In addition, stock prices are nonnegative numbers and it is conceivable that there is some very high upper level that they cannot exceed. In addition, whatever simulation we might perform is a finite-state simulation given that the precision of computers is finite.

The finite number of states represents uncertainty. There is uncertainty because the world can be in any of the M states. At time 0 it is not known in what state the world will be at time 1. Uncertainty is quantified by probabilities but a lot of arbitrage pricing theory can be developed without any reference to probabilities. Suppose there are N securities. Each security i pays d_{ij} number of dollars (or of any other unit of account) in each state of the world j . The payoff of each security need not be a positive number. For instance, a derivative instrument might have negative payoffs in some states of the world. Therefore, in a one-period setting, the securities are formally represented by an $N \times M$ matrix $\mathbf{D} = \{d_{ij}\}$ where the d_{ij} entry is the payoff of security i in state j . The matrix \mathbf{D} can also be written as a set of N row vectors:

$$\mathbf{D} = \begin{bmatrix} \mathbf{d}_1 \\ \cdot \\ \mathbf{d}_N \end{bmatrix}, \quad \mathbf{d}_i = [d_{i1} \cdot d_{iM}]$$

where the M -vector \mathbf{d}_i represents the payoffs of security i in each of the M states.

Each security is characterized by a price S . Therefore, the set of N securities is characterized by an N -vector \mathbf{S} and an $N \times M$ matrix \mathbf{D} . Suppose, for instance, there are two states and three securities. Then the three securities are represented by

$$\mathbf{S} = \begin{bmatrix} S_1 \\ S_2 \\ S_3 \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \\ d_{31} & d_{32} \end{bmatrix}$$

Every row of the \mathbf{D} matrix represents one security, every column one state. Note that in a one-period setting, prices are defined at time 0

while payoffs are defined at time 1. There is no payoff at time 0 and there is no price at time 1. A portfolio is represented by an N -vector of weights $\boldsymbol{\theta}$. In our example of a market with two states and three securities, a portfolio is a 3-vector:

$$\boldsymbol{\theta} = \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix}$$

The market value $S_{\boldsymbol{\theta}}$ of a portfolio $\boldsymbol{\theta}$ at time 0 is a scalar given by the scalar product:

$$S_{\boldsymbol{\theta}} = \mathbf{S}\boldsymbol{\theta} = \sum_{i=1}^N S_i \theta_i$$

Its payoff $\mathbf{d}_{\boldsymbol{\theta}}$ at time 1 is the M -vector:

$$\mathbf{d}_{\boldsymbol{\theta}} = \mathbf{D}'\boldsymbol{\theta}$$

The price of a security and the market value of a portfolio can be a negative number. In the previous example of a two-state, three-security market we obtain

$$\begin{aligned} S_{\boldsymbol{\theta}} &= \mathbf{S}\boldsymbol{\theta} = S_1\theta_1 + S_2\theta_2 + S_3\theta_3 \\ \mathbf{d}_{\boldsymbol{\theta}} &= \mathbf{D}'\boldsymbol{\theta} = \begin{bmatrix} d_{11} & d_{21} & d_{31} \\ d_{12} & d_{22} & d_{32} \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix} \\ &= \begin{bmatrix} d_{11}\theta_1 + d_{21}\theta_2 + d_{31}\theta_3 \\ d_{12}\theta_1 + d_{22}\theta_2 + d_{32}\theta_3 \end{bmatrix} \end{aligned}$$

Let's introduce the concept of arbitrage in this simple setting. As we have seen, arbitrage is essentially the possibility of making money by trading without any risk. Therefore, we define an arbitrage as any portfolio $\boldsymbol{\theta}$ that has a negative market value $S_{\boldsymbol{\theta}} = \mathbf{S}\boldsymbol{\theta} < 0$ and a non-negative payoff $D_{\boldsymbol{\theta}} = \mathbf{D}'\boldsymbol{\theta} \geq 0$ or, alternatively, a nonpositive market value $S_{\boldsymbol{\theta}} = \mathbf{S}\boldsymbol{\theta} \leq 0$ and a positive payoff $D_{\boldsymbol{\theta}} = \mathbf{D}'\boldsymbol{\theta} > 0$.

State Prices

Next we define *state prices*. A state-price vector is a strictly positive M -vector $\boldsymbol{\psi}$ such that security prices can be written as $\mathbf{S} = \mathbf{D}\boldsymbol{\psi}$. In other words, given a state-price vector, if it exists,

security prices can be recovered as a weighted average of the securities' payoffs, where the state-price vector gives the weights. In the previous two-state, three-security example we can write:

$$\boldsymbol{\psi} = \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}$$

$$\mathbf{S} = \mathbf{D}\boldsymbol{\psi}$$

$$\begin{bmatrix} S_1 \\ S_2 \\ S_3 \end{bmatrix} = \begin{bmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \\ d_{31} & d_{32} \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} d_{11}\psi_1 + d_{12}\psi_2 \\ d_{21}\psi_1 + d_{22}\psi_2 \\ d_{31}\psi_1 + d_{32}\psi_2 \end{bmatrix}$$

Given security prices and payoffs, state prices can be determined solving the system:

$$\begin{aligned} d_{11}\psi_1 + d_{12}\psi_2 &= S_1 \\ d_{21}\psi_1 + d_{22}\psi_2 &= S_2 \\ d_{31}\psi_1 + d_{32}\psi_2 &= S_3 \end{aligned}$$

This system admits solutions if and only if there are two linearly independent equations and the third equation is a linear combination of the other two. Note that this condition is necessary but not sufficient to ensure that there are state prices as state prices must be strictly positive numbers.

A portfolio $\boldsymbol{\theta}$ is characterized by payoffs $\mathbf{d}_\theta = \mathbf{D}'\boldsymbol{\theta}$. Its price is given, in terms of state prices, by: $S_\theta = \mathbf{S}\boldsymbol{\theta} = \mathbf{D}\boldsymbol{\psi}\boldsymbol{\theta} = \mathbf{d}_\theta\boldsymbol{\psi}$.

It can be demonstrated that there is no arbitrage if and only if there is a state-price vector. The formal demonstration is quite complicated given the inequalities that define an arbitrage portfolio. It hinges on the separating hyperplane theorem, which says that, given any two convex disjoint sets in R^M , it is possible to find a hyperplane separating them. A hyperplane is the locus of points x_i that satisfy a linear equation of the type:

$$a_0 + \sum_{i=1}^M a_i x_i = 0$$

Intuitively, however, it is clear that the existence of state prices ensures that the law of

one price introduced in the previous section is automatically satisfied. In fact, if there are state prices, two identical payoffs have the same price, regardless of how they are constructed. This is because the price of a security or of any portfolio is univocally determined as a weighted average of the payoffs, with the state prices as weights.

Risk-Neutral Probabilities

Let's now introduce the concept of risk-neutral probabilities. Given a state-price vector, consider the sum of its components $\psi_0 = \psi_1 + \psi_2 + \dots + \psi_M$. Normalize the state-price vector by dividing each component by the sum ψ_0 . The normalized state-price vector

$$\boldsymbol{\psi} = \{\psi_j\} = \left\{ \frac{\psi_j}{\psi_0} \right\}$$

is a set of positive numbers whose sum is one. These numbers can be interpreted as probabilities. They are not, in general, the real probabilities associated with states. They are called *risk-neutral probabilities*. We can then write

$$\mathbf{S} \frac{1}{\psi_0} = \mathbf{D}\boldsymbol{\psi}$$

We can interpret the above relationship as follows: The normalized security prices are their expected payoffs under these special probabilities. In fact, we can rewrite the above equation as

$$\bar{S}_i = \frac{S_i}{\psi_0} = E[d_i]$$

where expectation is taken with respect to risk-neutral probabilities. In this case, security prices are the discounted expected payoffs under these special risk-neutral probabilities.

Suppose that there is a portfolio $\bar{\boldsymbol{\theta}}$ such that $\mathbf{d}_{\bar{\theta}} = \mathbf{D}'\bar{\boldsymbol{\theta}} = \{1, 1, \dots, 1\}$. This portfolio can be one individual risk-free security. As we have seen above, $\mathbf{S}\boldsymbol{\theta} = \mathbf{d}_\theta\boldsymbol{\psi}$, which implies that $\psi_0 = \bar{\boldsymbol{\theta}}\mathbf{S}$ is the discount on riskless borrowing.

Complete Markets

Let's now define the concept of *complete markets*, a concept that plays a fundamental role in finance theory. In the simple setting of the one-period finite-state market, a complete market is one in which the set of possible portfolios is able to replicate an arbitrary payoff. Call $\text{span}(D)$ the set of possible portfolio payoffs, which is given by the following expression:

$$\text{span}(D) \equiv \{\mathbf{D}'\boldsymbol{\theta} : \boldsymbol{\theta} \in R^M\}$$

A market is complete if $\text{span}(D) = R^M$.

A one-period finite-state complete market is one where the equation

$$\mathbf{D}'\boldsymbol{\theta} = \boldsymbol{\xi} : \boldsymbol{\xi} \in R^M$$

always admits a solution. Recall from matrix algebra that this is the case if and only if the rank of \mathbf{D} is M . This means that there are at least M linearly independent payoffs—that is, there are as many linearly independent payoffs as there are states. Let's write down explicitly the system in the two-state, three-security market.

$$\begin{aligned} \mathbf{D}'\boldsymbol{\theta} &= \boldsymbol{\xi} \\ \begin{bmatrix} d_{11} & d_{21} & d_{31} \\ d_{12} & d_{22} & d_{32} \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix} &= \begin{bmatrix} \xi_1 \\ \xi_2 \end{bmatrix} \\ d_{11}\theta_1 + d_{21}\theta_2 + d_{31}\theta_3 &= \xi_1 \\ d_{12}\theta_1 + d_{22}\theta_2 + d_{32}\theta_3 &= \xi_2 \end{aligned}$$

This system of linear equations admits solutions if and only if the rank of the coefficient matrix is 2. This condition is not verified, for example, if the securities have the same payoff in each state. In this case, the relationship $\xi_1 = \xi_2$ must always be verified. In other words, the three securities can only replicate portfolios that have the same payoff in each state.

In this simple setting it is easy to associate risk-neutral probabilities with real probabilities. In fact, suppose that the vector of real probabilities \mathbf{p} is associated to states so that p_i is the probability of the i -th state. For any given

M -dimensional vector \mathbf{x} , we write its expected value under the real probabilities as

$$E[\mathbf{x}] = \mathbf{p}\mathbf{x} = \sum_{i=1}^M p_i x_i$$

It can be demonstrated that there is no arbitrage if and only if there is a strictly positive M -vector $\boldsymbol{\pi}$ such that: $\mathbf{S} = E[\mathbf{D}\boldsymbol{\pi}]$. Any such vector $\boldsymbol{\pi}$ is called a *state-price deflator*. To see this point, define

$$\pi_i = \frac{\psi_i}{p_i}$$

Prices can then be expressed as

$$S_i = \sum_{j=1}^M d_{ij}\psi_j = \sum_{j=1}^M p_j d_{ij} \frac{\psi_j}{p_i} = \sum_{j=1}^M p_j d_{ij} \pi_j$$

which demonstrates that $\mathbf{S} = E[\mathbf{D}\boldsymbol{\pi}]$.

We can now specialize the above calculations in the numerical case of the previous section. Recall that in the previous section we gave the example of three securities with the following prices and payoffs expressed in dollars:

$$\mathbf{S} = \begin{bmatrix} 70 \\ 60 \\ 80 \end{bmatrix} \quad \mathbf{D} = \begin{bmatrix} 50 & 100 \\ 30 & 120 \\ 38 & 112 \end{bmatrix}$$

We first compute the relative state prices:

$$\begin{aligned} 50\psi_1 + 100\psi_2 &= 70 \\ 30\psi_1 + 120\psi_2 &= 60 \\ 38\psi_1 + 112\psi_2 &= 80 \end{aligned}$$

Solving the first two equations, we obtain

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} 4/5 \\ 3/10 \end{bmatrix}$$

However, the third equation is not satisfied by these values for the state prices. As a consequence, there does not exist a state-price vector, which confirms that there are arbitrage opportunities as observed in the first section.

Now suppose that the price of security C is \$64 and not \$80. In this case, the third equation is satisfied and the state-price vector is the one shown above. Risk-neutral probabilities can now be easily computed. Here is how. First sum the two state prices: $\frac{4}{5} + \frac{3}{10} = \frac{11}{10}$ to obtain

$$\psi_0 = \psi_1 + \psi_2 = \frac{11}{10}$$

and consequently the risk-neutral probabilities:

$$\boldsymbol{\psi} = \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} \psi_1/\psi_0 \\ \psi_2/\psi_0 \end{bmatrix} = \begin{bmatrix} \frac{8}{11} \\ \frac{3}{11} \end{bmatrix}$$

Risk-neutral probabilities sum to one while state prices do not. We can now check if our market is complete. Write the following equations:

$$\begin{aligned} 50\theta_1 + 30\theta_2 + 38\theta_3 &= \xi_1 \\ 100\theta_1 + 120\theta_2 + 112\theta_3 &= \xi_2 \end{aligned}$$

The rank of the coefficient matrix is clearly 2 as the determinant of the first minor is different from zero:

$$\begin{bmatrix} 50 & 30 \\ 100 & 120 \end{bmatrix} = 50 \times 120 - 100 \times 30 = 300 \neq 0$$

Our sample market is therefore complete and arbitrage-free. A portfolio composed of the first two securities can replicate any payoff and the third security can be replicated as a portfolio of the first two.

ARBITRAGE PRICING IN A MULTIPERIOD FINITE-STATE SETTING

The above basic results can be extended to a multiperiod finite-state setting using probabilistic concepts. The economy is represented by a probability space $(\Omega, \mathfrak{S}, P)$ where Ω is the set of possible states, \mathfrak{S} is the algebra of events (recall that we are in a finite-state setting and therefore there are only a finite number of events), and P is a probability function. As the number of states is finite, finite probabilities $P(\{\omega\}) \equiv$

$P(\omega) \equiv p_\omega$ are defined for each state. There is only a finite number of dates from 0 to T .

Propagation of Information

The *propagation of information* is represented by a filtration \mathfrak{S}_t that, in the finite case, is equivalent to an information structure I_t . The latter is a discrete, hierarchical organization of partitions I_t with the following properties:

$$\begin{aligned} I_k &\equiv (\{A_{ik}\}); \quad k = 0, \dots, T; \quad i = 1, \dots, M_k; \\ 1 &= M_1 \leq \dots \leq M_k \leq \dots \leq M_T = M \\ A_{ik} \cap A_{jk} &= \emptyset \text{ if } i \neq j \text{ and } \bigcup_{i=1}^{M_k} A_{ik} = \Omega \end{aligned}$$

and, in addition, given any two sets A_{ik} , A_{jh} , with $h > k$, either their intersection is empty $A_{ik} \cap A_{jh} = \emptyset$ or $A_{ik} \supseteq A_{jh}$. In other words, the partitions become more refined with time.

Each security i is characterized by a payoff process d_t^i and by a price process S_t^i . In this finite-state setting, d_t^i and S_t^i are discrete variables that, given that there are M states, can be represented by M -vectors $\mathbf{d}_t^i = [d_t^i(\omega)]$ and $\mathbf{S}_t^i = [S_t^i(\omega)]$ where $d_t^i(\omega)$ and $S_t^i(\omega)$ are, respectively, the payoff and the price of the i -th asset at time t , $0 \leq t \leq T$ and in state $\omega \in \Omega$. All payoffs and prices are stochastic processes adapted to the filtration \mathfrak{S}_t . Given that d_t^i and S_t^i are adapted processes in a finite probability space, they have to assume a constant value on each partition of the information structure I_t . It is convenient to introduce the following notation:

$$\begin{aligned} d_{A_{jt}}^i &= d_t^i(\omega), \quad \omega \in A_{jt} \\ S_{A_{jt}}^i &= S_t^i(\omega), \quad \omega \in A_{jt} \end{aligned}$$

where $d_{A_{jt}}^i$ and $S_{A_{jt}}^i$ represent the constant values that the processes d_t^i and S_t^i assume on the states that belong to the sets A_{jt} of each partition I_t . There is $M_0 = 1$ value for $d_{A_{j0}}^i$ and $S_{A_{j0}}^i$, M_t values for $d_{A_{jt}}^i$ and $S_{A_{jt}}^i$ and $M_T = M$ values for $d_{A_{jT}}^i$ and $S_{A_{jT}}^i$. The same notation and the same consideration can be applied to any process adapted to the filtration \mathfrak{S}_t .

Trading Strategies

We have to define the meaning of trading strategies in this multiperiod setting. A trading strategy is a sequence of portfolios θ such that θ_t is the portfolio held at time t after trading. To ensure that there is no anticipation of information, each trading strategy θ must be an adapted process. The payoff d^θ generated by a trading strategy is an adapted process d_t^θ with the following time dynamics:

$$d_t^\theta = \theta_{t-1}(S_t + d_t) - \theta_t S_t$$

An arbitrage is a trading strategy whose payoff process is nonnegative and not always zero. In other words, an arbitrage is a trading strategy that is never negative and which is strictly positive for some instants and some states. Note that imposing the condition that payoffs are always nonnegative forbids any initial positive investment that is a negative payoff.

A consumption process is any nonnegative adapted process. Markets are said to be complete if any consumption process can be obtained as the payoff process of a trading strategy with some initial investment. Market completeness means that any nonnegative payoff process can be replicated with a trading strategy.

State-Price Deflator

We will now extend the concept of state-price deflator to a multiperiod setting. A state-price deflator is a strictly positive adapted process π_t such that the following set of M equations hold:

$$S_t^i = \frac{1}{\pi_t} E_t \left[\sum_{j=t+1}^T \pi_j d_j^i \right]$$

In other words, a state-price deflator is a strictly positive process such that prices S_t^i are random variables equal to the conditional expectation of discounted payoffs with respect to the filtration \mathfrak{F} . As noted above, in this finite-state setting a filtration is equivalent to an information structure I_t . Note that in the above stochastic equation—which is a set of M equations, one

for each state, the term on the left, the prices S_t^i , is an adapted process that, as mentioned, assumes constant values on each set of the partition I_t . The term on the right is a conditional expectation multiplied by a factor $1/\pi_t$. The process π_t is adapted by definition and, therefore, assumes constant values $\pi_{A_{it}}$ on each set of the partition I_t .

In this finite setting, conditional expectations are expectations computed with conditional probabilities. Conditional expectations are adapted processes. Therefore they assume one value at $t = 0$, M_j values for $t = j$, and M values at the last date.

To illustrate the above, let's write down explicitly the above equation in terms of the notation $d_{A_{jt}}^i$ and $S_{A_{jt}}^i$. Note first that

$$P(\{\omega\}|A_{kt}) = \frac{P(\{\omega\} \cap A_{kt})}{P(A_{kt})} = \frac{P(\{\omega\})}{P(A_{kt})},$$

if $\omega \in A_{kt}$, 0 if $\omega \notin A_{kt}$

Given that the probability space is finite,

$$P(A_{jt}) = \sum_{\omega \in A_{jt}} p_\omega$$

As we defined $P(\{\omega\}) \equiv p_\omega$, the previous equation becomes

$$\begin{aligned} P(\{\omega\}|A_{kt}) &= \frac{P(\{\omega\} \cap A_{kt})}{P(A_{kt})} = \frac{P(\{\omega\})}{P(A_{kt})} \\ &= \frac{p_\omega}{\left(\sum_{\omega \in A_{kt}} p_{\omega} \right)} \end{aligned}$$

if $\omega \in A_{kt}$, 0 if $\omega \notin A_{kt}$.

Pricing Relationships

We can now write the pricing relationship as follows:

$$\begin{aligned} S_{A_{kt}}^i &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \left(P(\{\omega\}|A_{kt}) \left(\sum_{j=t+1}^T \pi_j(\omega) d_j^i(\omega) \right) \right) \right] \\ &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \left(\frac{p_\omega}{\left(\sum_{\omega \in A_{kt}} p_\omega \right)} \left(\sum_{j=t+1}^T \pi_j(\omega) d_j^i(\omega) \right) \right) \right] \end{aligned}$$

$A_{kt} \in I_t, 1 \leq k \leq M_t$

The above formulas generalize to any trading strategy. In particular, if there is a state-price deflator, the market value of any trading strategy is given by

$$\begin{aligned} \theta_t \times \mathbf{S}_t &= \frac{1}{\pi_t} E \left[\sum_{j=t+1}^T \pi_j d_j^\theta \right] \\ (\theta_t \mathbf{S}_t)_{A_{kt}} &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \left(P(\{\omega\} | A_{kt}) \left(\sum_{j=t+1}^T \pi_j(\omega) d_j^\theta(\omega) \right) \right) \right] \\ &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \left(\frac{p_\omega}{\left(\sum_{\omega \in A_{kt}} p_\omega \right)} \left(\sum_{j=t+1}^T \pi_j(\omega) d_j^\theta(\omega) \right) \right) \right] \end{aligned}$$

It is possible to demonstrate that the payoff-price pair (d_t^i, S_t^i) admits no arbitrage if and only if there is a state-price deflator. These concepts and formulas generalize those of a one-period setting to a multiperiod setting.

Given a payoff-price pair (d_t^i, S_t^i) it is possible to compute the stateprice deflator, if it exists, from the previous equations. In fact, it is possible to write a set of linear equations in the π_t, π_{t-1} for each period. One can proceed backward from the period T to period 1 writing a homogeneous system of linear equations. As the system is homogeneous, one of the variables can be arbitrarily fixed; for example, the initial value π_0 can be assumed equal to 1. If the system admits nontrivial solutions and if all solutions are strictly positive, then there are state-price deflators.

To illustrate the above, let's write down explicitly the previous formulas for prices, extending the example of the previous section to a two-period setting. We assume there are three securities and two periods, that is, three dates $(0,1,2)$ and four states, indicated with the integers $1,2,3,4$, so that $\Omega = \{1,2,3,4\}$. Assume that the information structure is given by the following partitions of events:

$$\begin{aligned} I_0 &\equiv (I_0 \equiv \{A_{1,0}\}), \quad I_1 \equiv \{A_{1,1}, A_{2,1}\}, \\ I_2 &\equiv \{A_{1,2}, A_{2,2}, A_{3,2}, A_{4,2}\} \end{aligned}$$

$$\begin{aligned} A_{1,0} &= \{1 + 2 + 3 + 4\}, \quad A_{1,1} = \{1 + 2\}, \\ A_{2,1} &= \{3 + 4\} \\ A_{1,2} &= \{1\}, \quad A_{2,2} = \{2\}, \quad A_{3,2} = \{3\}, \quad A_{4,2} = \{4\} \end{aligned}$$

where we use $+$ to indicate logical union, so that, for example, $\{1 + 2\}$ is the event formed by states 1 and 2. The interpretation of the above notation is the following. At time zero the world can be in any possible state, that is, the securities can take any possible path. Therefore the partition at time zero is formed by the event $\{1 + 2 + 3 + 4\}$. At time 1, the set of states is partitioned into two mutually exclusive events, $\{1 + 2\}$ or $\{3 + 4\}$. At time 2 the partition is formed by all individual states. Note that this is a particular example; different partitions would be logically admissible.

Figure 1 represents the above structure. Each security is characterized by a price process and a payoff process adapted to the information structure. Each process is a collection of three discrete random variables indexed with the time indexes $0,1,2$. Each discrete random variable is a 4-vector as it assumes as many values as states. However, as processes are adapted, they must assume the same value on each partition of the information structure. Note also that payoffs are zero at date zero and prices are zero at date 2. Therefore, in this example, we can put together these vectors in two 3×4 matrices for

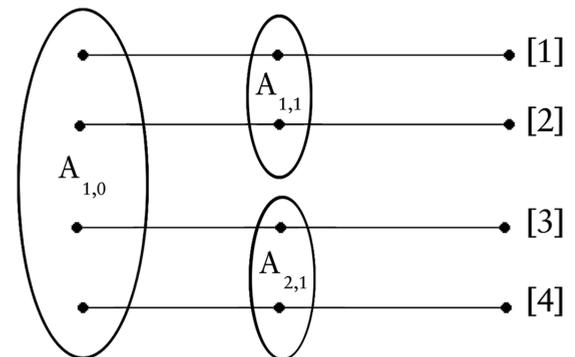

Figure 1 An Information Structure with Four States and Three Dates

each security as follows

$$\{S_t^i(\omega)\} \equiv \begin{bmatrix} S_0^i(1) & S_1^i(1) & 0 \\ S_0^i(2) & S_1^i(2) & 0 \\ S_0^i(3) & S_1^i(3) & 0 \\ S_0^i(4) & S_1^i(4) & 0 \end{bmatrix};$$

$$\{d_t^i(\omega)\} \equiv \begin{bmatrix} 0 & d_1^i(1) & d_2^i(1) \\ 0 & d_1^i(2) & d_2^i(2) \\ 0 & d_1^i(3) & d_2^i(3) \\ 0 & d_1^i(4) & d_2^i(4) \end{bmatrix}$$

The following relationships hold:

$$\begin{aligned} S_0^i(1) &= S_0^i(2) = S_0^i(3) = S_0^i(4) = S_{A_{1,0}}^i; \\ S_1^i(1) &= S_1^i(2) = S_{A_{1,1}}^i; \\ S_1^i(3) &= S_1^i(4) = S_{A_{2,1}}^i; \\ d_1^i(1) &= d_1^i(2) = d_{A_{1,1}}^i; \quad d_1^i(3) = d_1^i(4) = d_{A_{2,1}}^i \end{aligned}$$

where, as above, $S_t^i(\omega)$ is the price of security i in state ω at moment t and $d_t^i(\omega)$ is the payoff of security i in state ω at time t with the restriction that processes must assume the same value on partitions. This is because processes are adapted to the information structure so that there is no anticipation of information. One must not be able to discriminate at time 0 events that will be revealed at time 1 and so on.

Observe that there is no payoff at time 0 and no price at time 2 and that the payoffs at time 2 have to be intended as the final liquidation of the security as in the one-period case. Payoffs at time 1, on the other hand, are intermediate payments. Note that the number of states is chosen arbitrarily for illustration purposes. Each state of the world represents a path of prices and payoffs for the set of three securities. To keep the example simple, we assume that of all the possible paths of prices and payoffs only four are possible.

The state-price deflator can be represented as follows:

$$\{\pi_t(\omega)\} \equiv \begin{bmatrix} \pi_0(1) & \pi_1(1) & \pi_2(1) \\ \pi_0(2) & \pi_1(2) & \pi_2(2) \\ \pi_0(3) & \pi_1(3) & \pi_2(3) \\ \pi_0(4) & \pi_1(4) & \pi_2(4) \end{bmatrix}$$

$$\pi_0(1) = \pi_0(2) = \pi_0(3) = \pi_0(4)$$

$$\pi_1(1) = \pi_1(2) = \pi_1(3) = \pi_1(4)$$

A probability p_ω is assigned to each of the four states of the world. The probability of each event is simply the sum of the probabilities of its states. We can write down the formula for security prices in this way:

$$\begin{aligned} S_{A_{1,2}}^i &= S_2^i(1) = S_{A_{2,2}}^i = S_2^i(2) = S_{A_{3,2}}^i = S_2^i(3) \\ &= S_{A_{4,2}}^i = S_2^i(4) = 0 \end{aligned}$$

$$\begin{aligned} S_{A_{1,1}}^i &= S_1^i(1) = S_1^i(2) \\ &= \frac{1}{\pi_{A_{1,1}}} [P(A_{1,2}|A_{1,1})\pi_2(1)d_2^i(1) \\ &\quad + P(A_{2,2}|A_{1,1})\pi_2(2)d_2^i(2)] \\ &= \frac{1}{\pi_{A_{1,1}}} \left[\frac{p_1}{p_1 + p_2} \pi_2(1)d_2^i(1) \right. \\ &\quad \left. + \frac{p_2}{p_1 + p_2} \pi_2(2)d_2^i(2) \right] \end{aligned}$$

$$\begin{aligned} S_{A_{2,1}}^i &= S_1^i(3) = S_1^i(4) \\ &= \frac{1}{\pi_{A_{2,1}}} [P(A_{3,2}|A_{2,1})\pi_2(3)d_2^i(3) \\ &\quad + P(A_{4,2}|A_{2,1})\pi_2(4)d_2^i(4)] \\ &= \frac{1}{\pi_{A_{2,1}}} \left[\frac{p_3}{p_3 + p_4} \pi_2(3)d_2^i(3) \right. \\ &\quad \left. + \frac{p_4}{p_3 + p_4} \pi_2(4)d_2^i(4) \right] \end{aligned}$$

$$\begin{aligned} S_{A_{1,0}}^i &= \{p_1[\pi_{A_{1,1}}d_{A_{1,1}}^i + \pi_2(1)d_2^i(1)] + p_2[\pi_{A_{1,1}}d_{A_{1,1}}^i \\ &\quad + \pi_2(2)d_2^i(2)] + p_3[\pi_{A_{1,2}}d_{A_{1,2}}^i + \pi_2(3)d_2^i(3)] \\ &\quad + p_4[\pi_{A_{1,2}}d_{A_{1,2}}^i + \pi_2(4)d_2^i(4)]\} \end{aligned}$$

These equations illustrate how to compute the state-price deflator knowing prices,

payoffs, and probabilities. They form a homogeneous system of linear equations in $\pi_2(1), \pi_2(2), \pi_2(3), \pi_2(4), \pi_{A_{1,1}}, \pi_{A_{2,1}}, \pi_{A_{1,0}}$.

$$\begin{aligned} p_1 d_2^i(1) \pi_2(1) + p_2 d_2^i(2) \pi_2(2) - S_{A_{1,1}}^i (p_1 + p_2) \\ \pi_{A_{1,1}} &= 0 \\ p_3 d_4^i(3) \pi_2(3) + p_4 d_4^i(4) \pi_2(4) - S_{A_{2,1}}^i (p_3 + p_4) \\ \pi_{A_{2,1}} &= 0 \\ p_1 d_2^i(1) \pi_2(1) + p_2 d_2^i(2) \pi_2(2) + p_3 d_2^i(3) \pi_2(3) \\ + p_4 d_4^i(4) \pi_2(4) + (p_1 + p_2) d_{A_{1,1}}^i \pi_{A_{1,1}} \\ + (p_3 + p_4) d_{A_{2,3}}^i \pi_{A_{2,3}} - S_{A_{1,0}}^i \pi_{A_{1,0}} &= 0 \end{aligned}$$

Substituting, we obtain

$$\begin{aligned} p_1 d_2^i(1) \pi_2(1) + p_2 d_2^i(2) \pi_2(2) - S_{A_{1,1}}^i (p_1 + p_2) \\ \pi_{A_{1,1}} &= 0 \\ p_3 d_4^i(3) \pi_2(3) + p_4 d_4^i(4) \pi_2(4) - S_{A_{2,1}}^i (p_3 + p_4) \\ \pi_{A_{2,1}} &= 0 \\ [(p_1 + p_2) S_{A_{1,1}}^i + (p_1 + p_2) d_{A_{1,1}}^i] \pi_{A_{1,1}} \\ + [(p_3 + p_4) S_{A_{2,1}}^i + (p_3 + p_4) d_{A_{2,1}}^i] \pi_{A_{2,1}} \\ - S_{A_{1,0}}^i \pi_{A_{1,0}} &= 0 \end{aligned}$$

This homogeneous system must admit a strictly positive solution to yield a state-price deflator. There are seven unknowns. However, as the system is homogeneous, if nontrivial so-

lutions exist, one of the unknowns can be arbitrarily fixed, for example $\pi_{A_{1,0}}$. Therefore, six independent equations are needed. Each asset provides two conditions, so a minimum of three assets are needed.

To illustrate the point, we assume that all states (which are also events in this discrete example) have the same probability 0.25. Thus the events of the information structure have the following probabilities: the single event at time zero has probability 1, the two events at time 1 have probability 0.5, and the four events at time 2 coincide with individual states and have probability 0.25. Conditional probabilities are shown in Table 1.

For illustration purposes, let's write the following matrices for payoffs for each security at each date in each state:

$$\begin{aligned} \{d_1^i(\omega)\} &\equiv \begin{bmatrix} 0 & 15 & 50 \\ 0 & 15 & 100 \\ 0 & 20 & 70 \\ 0 & 20 & 110 \end{bmatrix}; \{d_2^i(\omega)\} \equiv \begin{bmatrix} 0 & 8 & 30 \\ 0 & 8 & 120 \\ 0 & 15 & 40 \\ 0 & 15 & 140 \end{bmatrix}; \\ \{d_3^i(\omega)\} &\equiv \begin{bmatrix} 0 & 5 & 38 \\ 0 & 5 & 112 \\ 0 & 8 & 42 \\ 0 & 8 & 130 \end{bmatrix} \end{aligned}$$

Table 1 Conditional Probabilities

$P(A_{1,1} A_{1,0}) = \frac{P(A_{1,1} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{1+2\}}{P\{1+2+3+4\}} = 0.5$	$P(A_{2,1} A_{1,0}) = \frac{P(A_{2,1} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{3+4\}}{P\{1+2+3+4\}} = 0.5$
$P(A_{1,2} A_{1,0}) = \frac{P(A_{1,2} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{1\}}{P\{1+2+3+4\}} = 0.25$	$P(A_{2,2} A_{1,0}) = \frac{P(A_{2,2} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{2\}}{P\{1+2+3+4\}} = 0.25$
$P(A_{3,2} A_{1,0}) = \frac{P(A_{3,2} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{3\}}{P\{1+2+3+4\}} = 0.25$	$P(A_{4,2} A_{1,0}) = \frac{P(A_{4,2} \cap A_{1,0})}{P(A_{1,0})} = \frac{P\{4\}}{P\{1+2+3+4\}} = 0.25$
$P(A_{1,2} A_{1,1}) = \frac{P(A_{1,2} \cap A_{1,1})}{P(A_{1,1})} = \frac{P\{1\}}{P\{1+2\}} = \frac{0.25}{0.5} = 0.5$	$P(A_{1,2} A_{2,1}) = \frac{P(A_{1,2} \cap A_{2,1})}{P(A_{2,1})} = \frac{P\{\emptyset\}}{P\{1+2\}} = 0$
$P(A_{2,2} A_{1,1}) = \frac{P(A_{2,2} \cap A_{1,1})}{P(A_{1,1})} = \frac{P\{2\}}{P\{1+2\}} = \frac{0.25}{0.5} = 0.5$	$P(A_{2,2} A_{2,1}) = \frac{P(A_{2,2} \cap A_{2,1})}{P(A_{2,1})} = \frac{P\{\emptyset\}}{P\{1+2\}} = 0$
$P(A_{3,2} A_{1,1}) = \frac{P(A_{3,2} \cap A_{1,1})}{P(A_{1,1})} = \frac{P\{\emptyset\}}{P\{1+2\}} = 0$	$P(A_{3,2} A_{2,1}) = \frac{P(A_{3,2} \cap A_{2,1})}{P(A_{2,1})} = \frac{P\{3\}}{P\{3+4\}} = 0.5$
$P(A_{4,2} A_{1,1}) = \frac{P(A_{4,2} \cap A_{1,1})}{P(A_{1,1})} = \frac{P\{\emptyset\}}{P\{1+2\}} = 0$	$P(A_{4,2} A_{2,1}) = \frac{P(A_{4,2} \cap A_{2,1})}{P(A_{2,1})} = \frac{P\{4\}}{P\{3+4\}} = 0.5$

We will assume that the state-price deflator is the following given process:

$$\{\pi_{t(\omega)}\} = \begin{bmatrix} 1 & 0.8 & 0.7 \\ 1 & 0.8 & 0.75 \\ 1 & 0.9 & 0.75 \\ 1 & 0.9 & 0.8 \end{bmatrix}$$

Each price is computed according to the previous equations. For example, calculations related to asset 1 are as follows:

$$S_2^1(1) = S_2^1(2) = S_2^1(3) = S_2^1(4) = 0$$

$$S_{A_{1,1}}^1 = \frac{1}{0.8}(0.5 \times 0.7 \times 50 + 0.5 \times 0.75 \times 100) = 68.75$$

$$S_{A_{2,1}}^1 = \frac{1}{0.9}(0.5 \times 0.75 \times 70 + 0.5 \times 0.8 \times 110) = 78.05$$

$$S_{A_{1,0}}^1 = \frac{1}{1}[0.25(0.8 \times 15 + 0.7 \times 50) + 0.25(0.8 \times 15 + 0.75 \times 100) + 0.25(0.9 \times 20 + 0.75 \times 70) + 0.25(0.9 \times 20 + 0.8 \times 110)] = 68.75$$

$$S_2^2(1) = S_2^2(2) = S_2^2(3) = S_2^2(4) = 0$$

$$S_{A_{1,1}}^2 = \frac{1}{0.8}(0.5 \times 0.7 \times 30 + 0.5 \times 0.75 \times 120) = 69.37$$

$$S_{A_{2,1}}^2 = \frac{1}{0.9}(0.5 \times 0.75 \times 40 + 0.5 \times 0.8 \times 140) = 78.88$$

$$S_{A_{1,0}}^2 = \frac{1}{1}[0.25(0.8 \times 8 + 0.7 \times 30) + 0.25(0.8 \times 8 + 0.75 \times 120) + 0.25(0.9 \times 15 + 0.75 \times 40) + 0.25(0.9 \times 15 + 0.8 \times 140)] = 73.2$$

$$S_2^3(1) = S_2^3(2) = S_2^3(3) = S_2^3(4) = 0$$

$$S_{A_{1,1}}^3 = \frac{1}{0.8}(0.5 \times 0.7 \times 38 + 0.5 \times 0.75 \times 112) = 69.12$$

$$S_{A_{2,1}}^3 = \frac{1}{0.9}(0.5 \times 0.75 \times 42 + 0.5 \times 0.8 \times 130) = 75.27$$

$$S_{A_{1,0}}^3 = \frac{1}{1}[0.25(0.8 \times 5 + 0.7 \times 38) + 0.25(0.8 \times 5 + 0.75 \times 112) + 0.25(0.9 \times 8 + 0.75 \times 42) + 0.25(0.9 \times 8 + 0.8 \times 130)] = 67.125$$

With the above equations we computed prices from payoffs and state-price deflators. If prices and payoffs were given, we could compute state-price deflators from the homogeneous system for state prices established above. Suppose that the following price processes were given:

$$\{S_t^1(\omega)\} = \begin{bmatrix} 68.75 & 68.75 & 0 \\ 68.75 & 68.75 & 0 \\ 68.75 & 78.05 & 0 \\ 68.75 & 78.05 & 0 \end{bmatrix}$$

$$\{S_t^2(\omega)\} = \begin{bmatrix} 73.2 & 69.37 & 0 \\ 73.2 & 69.37 & 0 \\ 73.2 & 78.88 & 0 \\ 73.2 & 78.88 & 0 \end{bmatrix}$$

$$\{S_t^3(\omega)\} = \begin{bmatrix} 67.125 & 69.12 & 0 \\ 67.125 & 69.12 & 0 \\ 67.125 & 75.27 & 0 \\ 67.125 & 75.27 & 0 \end{bmatrix}$$

We could then write the following system of equations to compute state-price deflators:

$$\begin{aligned} 0.25 \times 50 \times \pi_2(1) + 0.25 \times 100 \times \pi_2(2) - 68.75 \times 0.5 \times \pi_{A_{1,1}} &= 0 \\ 0.25 \times 70 \times \pi_2(1) + 0.25 \times 110 \times \pi_2(2) - 78.05 \times 0.5 \times \pi_{A_{1,1}} &= 0 \\ (55 \times 0.5 + 0.5 \times 15) \times \pi_{A_{1,1}} + (70.25 \times 0.5 + 0.5 \times 20) \times \pi_{A_{2,1}} - 68.75 \times \pi_{A_{1,0}} &= 0 \\ 0.25 \times 30 \times \pi_2(1) + 0.25 \times 120 \times \pi_2(2) - 69.37 \times 0.5 \times \pi_{A_{1,1}} &= 0 \\ 0.25 \times 40 \times \pi_2(1) + 0.25 \times 140 \times \pi_2(2) - 78.88 \times 0.5 \times \pi_{A_{1,1}} &= 0 \\ (55.5 \times 0.5 + 0.5 \times 8) \times \pi_{A_{1,1}} + (71 \times 0.5 + 0.5 \times 15) \times \pi_{A_{2,1}} - 73.2 \times \pi_{A_{1,0}} &= 0 \end{aligned}$$

$$\begin{aligned}
& 0.25 \times 38 \times \pi_2(1) + 0.25 \times 115 \times \pi_2(2) \\
& \quad - 69.12 \times 0.5 \times \pi_{A_{1,1}} = 0 \\
& 0.25 \times 42 \times \pi_2(1) + 0.25 \times 130 \times \pi_2(2) \\
& \quad - 75.27 \times 0.5 \times \pi_{A_{1,1}} = 0 \\
& (55 \times 0.5 + 0.5 \times 15) \times \pi_{A_{1,1}} + (70.25 \times 0.5 \\
& \quad + 0.5 \times 20) \times \pi_{A_{2,1}} - 67.125 \times \pi_{A_{1,0}} = 0
\end{aligned}$$

It can be verified that this system, obviously, is solvable and returns the same state-price deflators as in the previous example.

Equivalent Martingale Measures

We now introduce the concept and properties of *equivalent martingale measures*. This concept has become fundamental for the technology of derivative pricing. The idea of equivalent martingale measures is the following. A martingale is a process X_t such that at any time t its conditional expectation at time s , $s > t$ coincides with its present value: $X_t = E_t[X_s]$. In discrete time, a martingale is a process such that its value at any time is equal to its conditional expectation one step ahead. In our case, this principle can be expressed in a different but equivalent way by stating that prices are the discounted expected values of future payoffs. The law of iterated expectation then implies that price plus payoff processes are martingales.

In fact, assume that we can write

$$S_t = E_t \left[\sum_{j=t+1}^T d_j \right]$$

then the following relationship holds:

$$\begin{aligned}
S_t &= E_t \left[\sum_{j=t+1}^T d_j \right] = E_t \left[d_{t+1} + E_{t+1} \left[\sum_{j=t+1+1}^T d_j \right] \right] \\
&= E_t[d_{t+1} + S_{t+1}]
\end{aligned}$$

Given a probability space, price processes are not, in general, martingales. However it can be demonstrated that, in the absence of arbitrage, there is an artificial probability measure in which all price processes, appropriately dis-

counted, become martingales. More precisely, we will see that in the absence of arbitrage there is an artificial probability measure Q in which the following discounted present value relationship holds:

$$S_t^i = E_t^Q \left[\sum_{j=t+1}^T \frac{d_j^i}{R_{t,j}} \right]$$

We can rewrite this equation explicitly as follows:

$$\begin{aligned}
S_t^i &= E_t^Q \left[\sum_{j=t+1}^T \frac{d_j^i}{R_{t,j}} \right] \\
&= E_t^Q \left[\frac{d_{t+1}^i}{R_{t,t+1}} + \frac{1}{R_{t,t+1}} \sum_{j=t+2}^T \frac{d_j^i}{R_{t+1,j}} \right] \\
&= E_t^Q \left[\frac{d_{t+1}^i}{R_{t,t+1}} + \frac{E_{t+1}^Q}{R_{t,t+1}} \left[\sum_{j=t+2}^T \frac{d_j^i}{R_{t,j}} \right] \right] \\
&= E_t^Q \left[\frac{d_{t+1}^i + S_{t+1}^i}{R_{t,t+1}} \right]
\end{aligned}$$

which shows that the discounted price plus payoff process is a martingale. The terms on the left are the price processes, the terms on the right are the conditional expectations under the probability measure Q of the payoffs discounted with the risk-free payoff.

The measure Q is a mathematical construct. The important point is that this new probability measure can be computed either from the real probabilities if the state-price deflators are known or directly from the price and payoff processes. This last observation illustrates that the concept of arbitrage depends only on the structure of the price and payoff processes and not on the actual probabilities. As we will see later in this entry, equivalent martingale measures greatly simplify the computation of the pricing of derivatives.

Let's assume that there is short-term risk-free borrowing in the sense that there is a trading strategy able to pay for any given interval (t, s) one sure dollar at time s given that

$(d_t d_{t+1} \dots d_{s-1})^{-1}$ has been invested at time t . Equivalently, we can define for any time interval (t, s) the payoff of a dollar invested risk-free at time t as $R_{t,s} = (d_t d_{t+1} \dots d_{s-1})$.

We now define the concept of *equivalent probability measures*. Given a probability measure P the probability measure Q is said to be equivalent to P if both assign probability zero to the same events. An equivalent probability measure Q is an equivalent martingale measure if all price processes discounted with $R_{t,j}$ become martingales. More precisely, Q is an equivalent martingale measure if and only if the market value of any trading strategy is a martingale:

$$\theta_t \times S_t = E_t^Q \left[\sum_{j=t+1}^T \frac{d_j^\theta}{R_{t,j}} \right]$$

Risk-Neutral Probabilities

Probabilities computed according to the equivalent martingale measure Q are the risk-neutral probabilities. Risk-neutral probabilities can be explicitly computed. Here is how. Call q_ω the risk-neutral probability of state ω . Let's write explicitly the relationship

$$S_t^i = E_t^Q \left[\frac{d_j^i}{R_{t,j}} \right]$$

as follows:

$$\begin{aligned} S_{A_{kt}}^i &= \sum_{\omega \in A_{kt}} \frac{q_\omega}{Q(A_{kt})} \left[\sum_{j=t+1}^T \frac{d_j^i(\omega)}{R_{t,j}} \right] \\ &= \sum_{\omega \in A_{kt}} \frac{q_\omega}{\left(\sum_{\omega \in A_{kt}} q_\omega \right)} \left[\sum_{j=t+1}^T \frac{d_j^i(\omega)}{R_{t,j}} \right] \end{aligned}$$

The above system of equations determines the risk-neutral probabilities. In fact, we can write, for each risky asset, M_t linear equations, where M_t is the number of sets in the partition I_t plus the normalization equation for probabilities. From the above equation, one can see that

the system can be written as

$$\sum_{\omega \in A_{kt}} q_\omega \left[\sum_{j=t+1}^T \frac{d_j^i(\omega)}{R_{t,j}} - S_{A_{kt}}^i \right] = 0$$

$$\sum_{\omega=1}^S q_\omega = 1$$

This system might be determined, indetermined, or impossible. The system will be impossible if there are arbitrage opportunities. This system will be indetermined if there is an insufficient number of securities. In this case, there will be an infinite number of equivalent martingale measures and the market will not be complete.

Now consider the relationship between risk-neutral probabilities and state-price deflators. Consider a probability measure P and a nonnegative random variable Y with expected value on the entire space equal to 1. Define a new probability measure as $Q(B) = E[1_B Y]$ for any event B and where 1_B is the indicator function of the event B . The random variable Y is called the Radon-Nikodym derivative of Q and it is written

$$Y = \frac{dQ}{dP}$$

It is clear from the definition that P and Q are equivalent probability measures as they assign probability zero to the same events. Note that in the case of a finite-state probability space the new probability measure is defined on each state and is equal to

$$q_\omega = Y(\omega) p_\omega$$

Suppose π_t is a state-price deflator. Let Q be the probability measure defined by the Radon-Nikodym derivative:

$$\xi_T = \frac{\pi_T R_{0,T}}{\pi_0}$$

The new state probabilities under Q are the following:

$$q_\omega = \frac{\pi_T(\omega) R_{0,T}}{\pi_0(\omega)} p_\omega$$

Define the density process ξ_t for Q as $\xi_t = E_t[\xi_T]$. As $\xi_t = E_t[\xi_T]$ is an adapted process, we can write:

$$\begin{aligned} (E_t[\xi_T])_{A_{kt}} &= \xi_{A_{kt}} = \sum_{\omega \in A_{kt}} \frac{p_\omega}{P(A_{kt})} \xi_T(\omega) \\ &= \sum_{\omega \in A_{kt}} \frac{p_\omega}{P(A_{kt})} \frac{\pi_T(\omega) R_{0,T}}{\pi_0(\omega)} = \frac{\pi_{A_{kt}} R_{0,t}}{\pi_0(\omega)} \\ &\quad \times \frac{1}{\pi_{A_{kt}}} \sum_{\omega \in A_{kt}} \frac{p_\omega}{P(A_{kt})} \pi_T[\pi_0(\omega)] R_{t,T} \\ &= \frac{\pi_{A_{kt}} R_{0,t}}{\pi_0} \end{aligned}$$

As $R_{t,s} = (d_t d_{t+1} \dots d_{s-1})$ is the payoff at time s of one dollar invested in a risk-free asset at time t , $s > t$, we can then write the following equation:

$$1 = \frac{1}{\pi_t} E_t[\pi_s R_{t,s}]$$

Therefore,

$$\begin{aligned} 1 &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} P(\{\omega\} | A_{kt}) \pi_s(\omega) R_{t,s} \right] \\ &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \frac{p_\omega}{P(A_{kt})} \pi_s(\omega) R_{t,s} \right] \\ 1 &\leq k \leq M_t \end{aligned}$$

Substituting in the previous equation, we obtain, for each interval (t, T) ,

$$\xi_{A_{kt}} = (E_t[\xi_T])_{A_{kt}} = \frac{\pi_{A_{kt}} R_{0,t}}{\pi_{A_{10}}}$$

which we can rewrite in the usual notation as

$$\xi_t = E_t[\xi_T] = \frac{\pi_t R_{0,t}}{\pi_{10}}$$

We can now state the following result. Consider any \mathcal{F}_j -measurable variable x_j . This condition can be expressed equivalently stating that x_j assumes constant values on each set of the partition I_j . Then the following relationship holds:

$$E_t^Q[x_j] = E_t^P \frac{1}{\xi_t} [\xi_j x_j]$$

To see this, consider the following demonstration, which hinges on the fact that x_j assumes a constant value on each A_{lj} and, therefore, can be taken out of sums. In addition, as demonstrated above, from

$$1 = \frac{1}{\pi_t} E_t[\pi_s R_{t,s}]$$

the following relationship holds:

$$\begin{aligned} P(A_{kt}) \pi_{A_{kt}} &= \sum_{\omega \in A_{kt}} p_\omega \pi_s(\omega) R_{t,s} \\ 1 &\leq k \leq M_t \end{aligned}$$

$$\begin{aligned} (E_t^Q[x_j])_{A_{kt}} &= \sum_{\omega \in A_{kt}} \frac{q_\omega}{Q(A_{kt})} x_j(\omega) = \sum_{\omega \in A_{kt}} \frac{p_\omega}{Q(A_{kt})} \frac{\pi_T(\omega) R_{0,T}}{\pi_0(\omega)} x_j(\omega) \\ &= \frac{1}{Q(A_{kt})} \sum_{A_{hj} \subset A_{kt}} \left[\sum_{\omega \in A_{hj}} \frac{R_{0,j} R_{j,T} p_\omega \pi_T(\omega) x_j(\omega)}{\pi_0(\omega)} \right] \\ &= \frac{1}{Q(A_{kt})} \sum_{A_{hj} \subset A_{kt}} \left[\frac{x_{A_{hj}} R_{0,j}}{\pi_0(\omega)} \sum_{\omega \in A_{hj}} R_{j,T} p_\omega \pi_T(\omega) \right] \\ &= \frac{1}{Q(A_{kt})} \sum_{A_{hj} \subset A_{kt}} \left[\frac{x_{A_{hj}} R_{0,j} \pi_{A_{hj}} P(A_{hj})}{\pi_0(\omega)} \right] \\ &= \frac{1}{Q(A_{kt})} \sum_{A_{hj} \subset A_{kt}} [x_{A_{hj}} \xi_{A_{hj}} P(A_{hj})] \\ &= \frac{1}{\xi_{A_{kt}}} \sum_{A_{hj} \subset A_{kt}} \frac{x_{A_{hj}} \xi_{A_{hj}} P(A_{hj})}{P(A_{kt})} \\ &= \frac{1}{\xi_{A_{kt}}} [E_t^P(\xi_j x_j)_{A_{kt}}] \end{aligned}$$

Let's now apply the above result to the relationship:

$$\begin{aligned} S_t^i &= \frac{1}{\pi_t} E_t \left[\sum_{j=t+1}^T \pi_j d_j^i \right] = \frac{\pi_0}{\pi_t} E_t \left[\sum_{j=t+1}^T \frac{\pi_j R_{t,j}}{\pi_0} \frac{d_j^i}{R_{t,j}} \right] \\ &= \frac{\pi_0}{\pi_t R_{0,j}} E_t \left[\sum_{j=t+1}^T \frac{\pi_j R_{0,j}}{\pi_0} \frac{d_j^i}{R_{t,j}} \right] = E_t^Q \left(\frac{d_j^i}{R_{t,j}} \right) \end{aligned}$$

We have thus demonstrated the following results: There is no arbitrage if and only if there is an equivalent martingale measure. In addition,

π_t is a state-price deflator if and only if an equivalent martingale measure Q has the density process defined by

$$\xi_t = \frac{\pi_t R_{0,t}}{\pi_0}$$

In addition, it can be demonstrated that, if there is no arbitrage, markets are complete if and only if there is a unique equivalent martingale measure.

To illustrate the above we now proceed to detail the calculations for the previous example of three assets, three dates, and four states. Let's first write the equations for the risk-free asset:

$$\begin{aligned} 1 &= \frac{1}{\pi_{A_{kt}}} \left[\sum_{\omega \in A_{kt}} \frac{p_\omega}{P(A_{kt})} \pi_s(\omega) R_{t,s} \right] \\ 1 &= \frac{1}{\pi_{A_{11}}} \left(\frac{p_1}{p_1 + p_2} \pi_2(1) R_{1,2} + \frac{p_2}{p_1 + p_2} \pi_2(2) R_{1,2} \right) \\ 1 &= \frac{1}{\pi_{A_{21}}} \left(\frac{p_3}{p_3 + p_4} \pi_2(3) R_{1,2} + \frac{p_4}{p_3 + p_4} \pi_2(4) R_{1,2} \right) \\ 1 &= \frac{1}{\pi_{A_{10}}} [p_1 \pi_2(1) R_{0,2} + p_2 \pi_2(2) R_{0,2} \\ &\quad + p_3 \pi_2(3) R_{0,2} + p_4 \pi_2(4) R_{0,2}] \end{aligned}$$

$$\pi_{A_{11}} = \pi_1(1) = \pi_1(2)$$

$$\pi_{A_{21}} = \pi_1(3) = \pi_1(4)$$

$$\pi_{A_{10}} = \pi_0(1) = \pi_0(2) = \pi_0(3) = \pi_0(4)$$

We can now rewrite the pricing relationships for the other risky assets as follows:

$$\text{At date 2, prices are zero: } S_2^i = 0.$$

At date 1, the relationship

$$S_1^i = E_1 \left[\frac{d_2^i}{R_{1,2}} \right]$$

holds. In fact, we can write the following:

$$\begin{aligned} S_{A_{1,1}}^i &= S_1^i(1) = S_1^i(2) \\ &= \frac{1}{\pi_1(2)} [P(A_{1,2}|A_{1,1}) \pi_2(1) d_2^i(1) \\ &\quad + P(A_{2,2}|A_{1,1}) \pi_2(2) d_2^i(2)] \\ &= \frac{1}{\pi_{11}} \left(\frac{p_1}{p_1 + p_2} \pi_2(1) R_{1,2} \frac{d_2^i(1)}{R_{1,2}} \right. \\ &\quad \left. + \frac{p_2}{p_1 + p_2} \pi_2(2) R_{1,2} \frac{d_2^i(2)}{R_{1,2}} \right) \end{aligned}$$

$$\begin{aligned} &= \left[Q(A_{1,2}|A_{1,1}) \frac{d_2^i(1)}{R_{1,2}} + Q(A_{2,2}|A_{1,1}) \frac{d_2^i(2)}{R_{1,2}} \right] \\ &= \left[\frac{q_1}{q_1 + q_2} \frac{d_2^i(1)}{R_{1,2}} + \frac{q_2}{q_1 + q_2} \frac{d_2^i(2)}{R_{1,2}} \right] \end{aligned}$$

$$S_{A_{2,1}}^i = S_1^i(3) = S_1^i(4)$$

$$\begin{aligned} &= \left[Q(A_{3,2}|A_{1,1}) \frac{d_2^i(3)}{R_{1,2}} + Q(A_{4,2}|A_{1,1}) \frac{d_2^i(4)}{R_{1,2}} \right] \\ &= \left[\frac{q_3}{q_3 + q_4} \frac{d_2^i(3)}{R_{1,2}} + \frac{q_4}{q_3 + q_4} \frac{d_2^i(4)}{R_{1,2}} \right] \end{aligned}$$

At date 0, the relationship

$$S_0^i = E_0 \left[\frac{d_1^i}{R_{0,1}} + \frac{d_2^i}{R_{0,2}} \right]$$

holds. In fact we can write the following:

$$\begin{aligned} S_{A_{1,0}}^i &= S_0^i(1) = S_0^i(2) = S_0^i(3) = S_0^i(4) \\ &= \frac{1}{\pi_{A_{10}}} \left\{ \begin{aligned} &p_1 [\pi_1(1) d_1^i(1) + \pi_2(1) d_2^i(1)] \\ &+ p_2 [\pi_1(2) d_1^i(2) + \pi_2(2) d_2^i(2)] \\ &+ p_3 [\pi_1(3) d_1^i(3) + \pi_2(3) d_2^i(3)] \\ &+ p_4 [\pi_1(4) d_1^i(4) + \pi_2(4) d_2^i(4)] \end{aligned} \right\} \\ &= p_1 \left[\frac{\pi_1(1) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(1)}{R_{0,1}} + \frac{\pi_2(1) R_{0,2}}{\pi_{A_{1,0}}} \frac{d_2^i(1)}{R_{0,2}} \right] \\ &\quad + p_2 \left[\frac{\pi_1(2) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(2)}{R_{0,1}} + \frac{\pi_2(2) R_{0,2}}{\pi_{A_{1,0}}} \frac{d_2^i(2)}{R_{0,2}} \right] \\ &\quad + p_3 \left[\frac{\pi_1(3) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(3)}{R_{0,1}} + \frac{\pi_2(3) R_{0,2}}{\pi_{A_{1,0}}} \frac{d_2^i(3)}{R_{0,2}} \right] \\ &\quad + p_4 \left[\frac{\pi_1(4) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(4)}{R_{0,1}} + \frac{\pi_2(4) R_{0,2}}{\pi_{A_{1,0}}} \frac{d_2^i(4)}{R_{0,2}} \right] \\ &= p_1 \left\{ \frac{\pi_1(1) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(1)}{R_{0,1}} \frac{1}{\pi_{11}} \left[\frac{p_1}{p_1 + p_2} \pi_2(1) R_{1,2} \right. \right. \\ &\quad \left. \left. + \frac{p_2}{p_1 + p_2} \pi_2(2) R_{1,2} \right] \right\} \\ &\quad + p_2 \left\{ \frac{\pi_1(2) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(2)}{R_{0,1}} \frac{1}{\pi_{21}} \left[\frac{p_1}{p_1 + p_2} \pi_2(1) R_{1,2} \right. \right. \\ &\quad \left. \left. + \frac{p_2}{p_1 + p_2} \pi_2(2) R_{1,2} \right] \right\} \\ &\quad + p_3 \left\{ \frac{\pi_1(3) R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(3)}{R_{0,1}} \frac{1}{\pi_{31}} \left[\frac{p_3}{p_3 + p_4} \pi_2(3) R_{1,2} \right. \right. \\ &\quad \left. \left. + \frac{p_4}{p_3 + p_4} \pi_2(4) R_{1,2} \right] \right\} \end{aligned}$$

$$\begin{aligned}
& + p_4 \left\{ \frac{\pi_1(4)R_{0,1}}{\pi_{A_{1,0}}} \frac{d_1^i(4)}{R_{0,1}} \frac{1}{\pi_{41}} \left[\frac{p_3}{p_3 + p_4} \pi_2(3)R_{1,2} \right. \right. \\
& \left. \left. + \frac{p_3}{p_3 + p_4} \pi_2(4)R_{1,2} \right] \right\} \\
& + q_1 \frac{d_2^i(1)}{R_{0,2}} + q_2 \frac{d_2^i(2)}{R_{0,2}} + q_3 \frac{d_2^i(3)}{R_{0,2}} + q_4 \frac{d_2^i(4)}{R_{0,2}} \\
& = \frac{d_1^i(1)}{R_{0,1}} \left[\frac{p_1 \pi_2(1)}{\pi_{A_{1,0}}} R_{0,2} + \frac{p_2 \pi_2(2)}{\pi_{A_{1,0}}} R_{0,2} \right] \\
& + \frac{d_1^i(3)}{R_{0,1}} \left[\frac{p_3 \pi_2(3)}{\pi_{A_{1,0}}} R_{0,2} + \frac{p_4 \pi_2(4)}{\pi_{A_{1,0}}} R_{0,2} \right] \\
& + q_1 \frac{d_2^i(1)}{R_{0,2}} + q_2 \frac{d_2^i(2)}{R_{0,2}} + q_3 \frac{d_2^i(3)}{R_{0,2}} + q_4 \frac{d_2^i(4)}{R_{0,2}} \\
& = q_1 \frac{d_1^i(1)}{R_{0,1}} + q_2 \frac{d_1^i(2)}{R_{0,1}} + q_3 \frac{d_1^i(3)}{R_{0,1}} + q_4 \frac{d_1^i(4)}{R_{0,1}} \\
& + q_1 \frac{d_2^i(1)}{R_{0,2}} + q_2 \frac{d_2^i(2)}{R_{0,2}} + q_3 \frac{d_2^i(3)}{R_{0,2}} + q_4 \frac{d_2^i(4)}{R_{0,2}}
\end{aligned}$$

The value of a derivative instrument might depend on the path of its past values. Consider a lookback option on a stock—that is, a derivative instrument on a stock whose payoff at time t is the maximum difference between the price of the stock and a given value K at any moment prior to t . Call V_t the payoff of the lookback option at time t . We can then write:

$$\begin{aligned}
V_t &= \max_{0 \leq k < t} (S_k - K)^+ \\
(S_k - K)^+ S_k - K & (S_k - K)^+ = \max(S_k - K, 0)
\end{aligned}$$

THE BINOMIAL MODEL

Let's now introduce the simple but important multiperiod finite-state model known as the binomial model. The binomial model is important because it gives a simple and mathematically tractable model of stock price behavior that tends, in the limit of a zero time step, to a Brownian motion.¹ We introduce a market populated by one risk-free asset and by one or more risky assets whose price(s) follow(s) a binomial or trinomial model. In the next section we will see how to compute the price of derivative instruments in this market.

In the binomial model of stock prices, we assume that at each time step the stock price will assume one of two possible values. This is a restriction of the general multiperiod finite-state model described in the previous sections on probability theory. The latter is, as we have seen in the previous section, a hierarchical structure of partitions of the set of states. The number of sets in any partition is arbitrary, provided that partitions grow more refined with time.

The binomial model assumes that there are two positive numbers, d and u , such that $0 < d < u$ and such that at each time step the price S_t of the risky asset changes to dS_t or to uS_t . In general one assumes that $0 < d < 1 < u$ so that d represents a price decrease (a movement down) while u represents a price increase (a movement up). It is often required that

$$d = \frac{1}{u}$$

In this case an equal number of movements up and down leave prices unchanged. The binomial model is a Markov model as the distribution of S_t clearly depends only on the value of S_{t-1} .

A binomial model can be graphically represented by a tree. For example, Figure 2 shows a binomial model for three periods. A binomial model over T time steps, from 0 to T , produces a total of 2^T paths. Therefore, the corresponding space of states has 2^T states. However, the

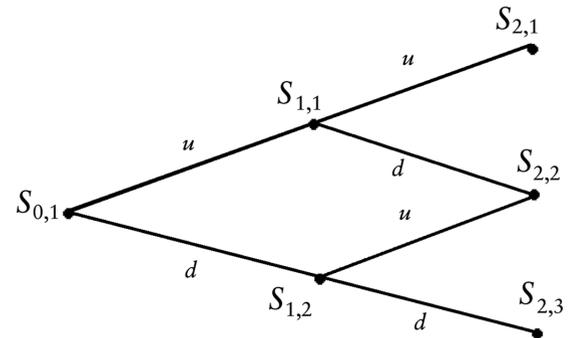

Figure 2 Binomial Model: Illustration of a Binomial Tree with Three Dates, Three Final Prices, and Four States: uu , ud , du , dd

number of different final prices $S_T = u^k d^{T-k} S_0$, $k = 0, 1, \dots, T$ is determined solely by the number of u and d in each path and increases by 1 at each time step; there are as many final prices as dates. For example, the model in Figure 2 shows three final prices and four states.

Note that there is a simple relationship between the numbers d and u and returns. In fact, we can write,

$$R_t(\text{up}) = \frac{S_{t+1} - S_t}{S_t} = \frac{uS_t - S_t}{S_t} = u - 1$$

$$R_t(\text{down}) = d - 1$$

Real probabilities of states are typically constructed from the probabilities of a movement up or down. Call p the probability of a movement up; $1 - p$ is thus the probability of a movement down. Suppose that the state s , which is identified by a price path, has k movements up and $T - k$ movements down. The probability of the state s is

$$p_s = p^k (1 - p)^{T-k}$$

Consider the final date T . Each of the possible final prices $S_T = u^k d^{T-k} S_0$, $k = 0, 1, \dots, T$ can be obtained through

$$\binom{T}{k} = \frac{T!}{k!(T-k)!}$$

paths with k movements up and $T - k$ movements down. The probability distribution of final prices is therefore a binomial distribution:

$$P(S_T = u^k d^{T-k} S_0) = \binom{T}{k} p^k (1 - p)^{T-k}$$

Following the same reasoning, one can demonstrate that at any intermediate date the probability distribution of prices is a binomial distribution as follows:

$$P(S_t = u^k d^{t-k} S_0) = \binom{t}{k} p^k (1 - p)^{t-k}$$

Next introduce a risk-free security. In the setting of a binomial model, a risk-free security is simply a security such that $d = u = 1 + r$ where

$r > 0$ is the positive risk-free rate. To avoid arbitrage it is clearly necessary that $d < 1 + r < u$. In fact, if the interest rate is inferior to both the up and down returns, one can make a sure profit by buying the risky asset and shorting the risk-free asset. If the interest rate is superior to both the up and down returns, one can make a sure profit by shorting the risky asset and buying the risk-free asset. Denote by b_t the price of the risk-free asset at time t . From the definition of price movement in the binomial model we can write: $b_t = (1 + r)^t b_0$.

Risk-Neutral Probabilities for the Binomial Model

Let's now compute the risk-neutral probabilities. In the setting of binomial models, the computation of risk-neutral probabilities is simple. In fact we have to impose the condition:

$$q_t = E_t^Q[q_{t+1}]$$

which we can explicitly write as follows:

$$S_t = \frac{quS_t + (1 - q)dS_t}{1 + r}$$

$$1 + r = qu + d - qd$$

$$q = \frac{1 + r - d}{u - d}$$

$$1 - q = \frac{u - 1 - r}{u - d}$$

As we have assumed $0 < d < 1 + r < u$, the condition $0 < q < 1$ holds. Therefore we can state that the unique risk-neutral probabilities are

$$q = \frac{1 + r - d}{u - d}$$

$$1 - q = \frac{u - 1 - r}{u - d}$$

The binomial model is complete and arbitrage free.

Suppose that there is more than one risky asset, for example two risky assets, in addition to the risk-free asset. At each time step each

risky asset can go either up or down. Therefore there are four possible joint movements at each time step: uu, ud, du, dd that we identify with the states 1,2,3,4. Four probabilities must be determined at each time step; four equations are therefore needed. Two equations are provided by the martingale conditions:

$$S_t^1 = \frac{q_1 u S_t^1 + q_2 u S_t^1 + q_3 u S_t^1 + q_4 u S_t^1}{1+r}$$

$$S_t^2 = \frac{q_1 u S_t^2 + q_3 u S_t^2 + q_2 u S_t^2 + q_4 u S_t^2}{1+r}$$

A third equation is provided by the fact that probabilities must sum to 1. The fourth condition, however, is missing. The model is incomplete.

The problem of approximating price processes when there are two stocks and one bond and where the stock prices follow two correlated lognormal processes has long been of interest to financial economists. As seen above, with two stocks and one bond available for trading, markets cannot be completed by dynamic trading. This is not the case in the continuous-time model, in which markets can be completed by continuous trading in the two stocks and the bond. Different solutions to this problem have been proposed in the literature.²

ARBITRAGE PRICING IN A DISCRETE-TIME, CONTINUOUS-STATE SETTING

Let's now discuss the discrete-time, continuous-state setting. This is an important setting as it is, for example, the setting of the arbitrage pricing theory (APT) model.³

As in the previous discrete-time, discrete-state setting, we apply probabilistic concepts. The economy is represented by a probability space (Ω, σ, P) where Ω is the set of possible states, σ is the σ -algebra of events (formed, in

this continuous-state setting, by a nondenumerable number of events), and P is a probability function. As the number of states is infinite, the probability of each state is zero and only events, in general, formed by nondenumerable states have a finite probability. There are only a finite number of dates from 0 to T . The propagation of information is represented by a finite filtration \mathfrak{S}_t , $t = 0, 1, \dots, T$. In this case, the filtration \mathfrak{S}_t is not equivalent to an information structure I_t .

Each security i is characterized by a payoff process d_t^i and by a price process S_t^i . In this continuous-state setting, d_t^i and S_t^i are formed by a finite number of continuous variables. As before, $d_t^i(\omega)$ and $S_t^i(\omega)$ are, respectively, the payoff and the price of the i -th asset at time t , $0 \leq t \leq T$ and in state $\omega \in \Omega$. All payoffs and prices are stochastic processes adapted to the filtration \mathfrak{S} .

To develop an intuition for continuous-state arbitrage pricing, consider the previous multiperiod, finite-state case with a very large number M of states, $M \gg N$ where N is the number of securities. Recall from our earlier discussion that risk-neutral probabilities can be computed solving the following system of linear equations:

$$\sum_{\omega \in A_{k,t}} q_\omega \left[\sum_{j=t+1}^T \frac{d_j^i(\omega)}{R_{t,j}} - S_{A_{k,t}}^i \right] = 0$$

$$\sum_{\omega=1}^M q_\omega = 1$$

Recall also that at each date t the information structure I_t partitions the set of states into M_t subsets. Each partition therefore yields $N \times M_t$ equations and the system is formed by a total of

$$N \times \sum_{t=0}^{T-1} M_t$$

equation plus the probability normalizing equation. Consider that the previous system can be broken down, at each date t , into separate blocks formed by N equations (one for

each asset) of the following type:

$$\sum_{\omega \in A_{kt}} q_{\omega}^* \sum_{j=t+1}^T \frac{d_j^i}{R_{t,j}} = S_{A_{kt}}$$

$$q_{\omega}^* = \frac{q_{\omega}}{\sum_{\omega \in A_{kt}} q_{\omega}}$$

Each of these systems can be solved individually for the conditional probabilities q_{ω}^* . Recall that a system of this type admits a solution if and only if the coefficient matrix and the augmented coefficient matrix have the same rank. If the system is solvable, its solution will be unique if and only if the number of unknowns is equal to the rank of the coefficient matrix.

If the above system is not solvable, then there are arbitrage opportunities. This occurs if the payoffs of an asset are a linear combination of those of other assets, but its price is not the same linear combination of the prices of the other assets. This happens, in particular, if two assets have the same payoff in each state but different prices. In these cases, in fact, the rank of the coefficient matrix is inferior to the rank of the augmented matrix.

Under the assumption

$$M \gg N \times \sum_{t=0}^{T-1} M_t$$

this system, if it is solvable, will be undetermined. Therefore, there will be infinite equivalent risk-neutral probabilities and the market will not be complete. Going to the limit of an infinite number of states, the above reasoning proves, heuristically, that a discrete-time continuous-state market with a finite number of securities is inherently incomplete. In addition, there will be arbitrage opportunities only if the random variable that represents the payoff of an asset is a linear combination of the random variables that represent the payoffs of other assets, but the random variables that represent prices are not in the same relationship.

The above discussion can be illustrated in the case of multiple assets, each following a binomial model. If there are N linearly indepen-

dent assets, the price paths in the interval $(0, T)$ will form a total of 2^{NT} states. In a binomial model, we can limit our considerations to one time step as the other steps are identical. In one step, each price S_t^i at time t can go up to $S_t^i u^i$ or down to $S_t^i d^i$ at time $t + 1$. Given the prices $\{S_t^i\} \equiv \{S_t^1, S_t^2, \dots, S_t^N\}$ at time t , there will be at the next time step, $2N$ possible combinations $\{S_t^1 w^1, S_t^2 w^2, \dots, S_t^N w^N\}$, $w^i = u^i$ or d^i .

Suppose that there are 2^N states and that each combination of prices identifies a state. This means that at each date t the information structure I_t partitions the set of states into 2^{Nt} subsets. Each set of the partition is partitioned into 2^N subsets at the next time step. This yields $2^N(t + 1)$ subsets at time $t + 1$.

Note that this partitioning is compatible with any correlation structure between the random variables that represent prices. In fact, correlations depend on the value of the probability assigned to each state while the partitioning we assume depends on how different prices are assigned to different states.

Risk-neutral probabilities q_i , $i = 1, 2, \dots, 2^N$ can be determined solving the following system of martingale conditions:

$$\sum_{j=1}^{2^N} q_j S_t^i w^i(j) = S_t^i$$

$$\sum_{j=1}^{2^N} q_j = 1$$

$$j = 1, 2, \dots, 2^N, i = 1, 2, \dots, N$$

which becomes, after dividing each equation by S_t^i , the following:

$$\sum_{i=1}^{2^N} q^1 w_j(j) = 1$$

$$\sum_{j=1}^{2^N} q_j = 1$$

where $w^i(j) = u^i$ or d^i for asset i in state j .

It can be verified that, under the previous assumptions and provided prices are positive, the above system admits infinite solutions. In fact,

as $N + 1 < 2^N$, the number of equations is larger than the number of unknowns. Therefore, if the system is solvable it admits infinite solutions. To verify that the system is indeed solvable, let's choose the first asset and partition the set of states into two events corresponding to the movement up or down of the same asset. Assign to these events probabilities as in the binomial model

$$q_t^1 = \frac{1 - r + d_t^1}{u_t^1 - d_t^1} \text{ and } 1 - q_t^1$$

Choose a second asset and partition each of the previous events into two events corresponding to the movements up or down of the second asset. We can now assign the following probabilities to each of the following four events:

$$q_t^1 q_t^2, q_t^1(1 - q_t^2), (1 - q_t^1)q_t^2, (1 - q_t^1)(1 - q_t^2)$$

It can be verified that these numbers sum to one. The same process can be repeated for each additional asset. We obtain a set of positive numbers that sum to one and that satisfy the system by construction. There are infinite other possible constructions. In fact, at each step, we could multiply probabilities by "correlation factors" (i.e., numbers that form a 2×2 correlation matrix) and still obtain solutions to the system.

We can therefore conclude that a system of positive binomial prices such as the one above plus a risk-free asset is arbitrage-free and forms an incomplete market. If we let the number of states tend to infinity, the binomial distribution converges to a normal distribution. We have therefore demonstrated heuristically that a multivariate normal distribution plus a risk-free asset forms an incomplete and arbitrage-free market. Note that the presence of correlations does not change this conclusion.

Let's now see under what conditions this conclusion can be changed. Go back to the multiple binomial model, assuming, as before, that there are N assets and T time steps. There is no logical reason to impose that the number of states be 2^{NT} . As we can consider each time step separately, suppose that there is only one time step

and that there are a number of states less than or equal to the number of assets plus 1: $M \leq N + 1$. In this case, the martingale condition that determines risk-neutral probabilities becomes:

$$\sum_{j=1}^M q_j w^i(j) \\ \sum_{j=1}^N q_j = 1$$

There are M equations and $N + 1$ unknowns with $M \leq N + 1$. This system will either determine unique risk-neutral probabilities or will be unsolvable. Therefore, the market will be either complete and arbitrage-free or will exhibit arbitrage opportunities. Note that in this case we cannot use the constructive procedure used in the previous case.

What is the economic meaning of the condition that the number of states be less than or equal to the number of assets? To illustrate this point, assume that the number of states is $M = 2^K \leq N + 1$. This means that we can choose K assets whose independent price processes identify all the states as in the previous case. Now add one more asset. This asset will go up or down not in specific states but in events formed by a number of states. Suppose it goes up in the event A and goes down in the event B . These events are determined by the value of the first K assets. In other words, the new asset will be a function of the first K assets. An interesting case is when the new asset can be expressed as a linear function of the first K assets. We can then say that the first K assets are factors and that any other asset is expressed as a linear combination of the factors.

Consider that, given the first K assets, it is possible to determine state-price deflators. These state-price deflators will not be uniquely determined. Any other price process must be expressed as a linear combination of state-price deflators to avoid arbitrage. If all price processes are arbitrage-free, the market will be

complete if it is possible to determine uniquely the risk-neutral probabilities.

If we let the number of states become very large, the number of assets must become large as well. Therefore it is not easy to develop simple heuristic arguments in the limit of a large economy. What we can say is that in a large discrete economy where the number of states is less than or equal to the number of assets, if there are no arbitrage opportunities the market might be complete. If the market is complete and arbitrage-free, there will be a number of factors while all other processes will be linear combinations of these factors.

KEY POINTS

- The law of one price states that a given asset must have the same price regardless of the means by which one goes about creating that asset.
- Arbitrage is the simultaneous buying and selling of an asset at two different prices in two different markets.
- A finite-state one-period market is represented by a vector of prices and a matrix of payoffs.
- A state-price vector is a strictly positive vector such that prices are the product of the state-price vector and the payoff matrix.
- There is no arbitrage if and only if there is a state-price vector.
- A market is complete if an arbitrary payoff can be replicated by a portfolio.
- A finite-state one-period market is complete if there are as many linearly independent assets as states.
- A multiperiod finite-state economy is represented by a probability space plus an information structure.
- In a multiperiod finite-state market each security is represented by a payoff process and a price process.
- An arbitrage is a trading strategy whose payoff process is nonnegative and not always zero.
- A market is complete if any nonnegative payoff process can be replicated with a trading strategy.
- A state-price deflator is a strictly positive process such that prices are random variables equal to the conditional expectation of discounted payoffs.
- A martingale is a process such that at any time t its conditional expectation at time s , $s > t$ coincides with its present value.
- In the absence of arbitrage there is an artificial probability measure in which all price processes, appropriately discounted, become martingales.
- Given a probability measure P , the probability measure Q is said to be equivalent to P if both assign probability zero to the same events.
- The binomial model assumes that there are two positive numbers, d and u , such that $0 < d < u$ and such that at each time step the price S of the risky asset changes to dS or to uS .
- The distribution of prices of a binomial model is a binomial distribution.
- The binomial model is complete.

NOTES

1. The binomial model was first suggested for the pricing of options by Cox, Ross, and Rubinstein (1979), Rendleman and Bartter (1979), and Sharpe (1978).
2. See He (1990).
3. For an application of the principles discussed here to the APT, see Focardi and Fabozzi (2004).

Arbitrage Pricing: Continuous-State, Continuous-Time Models

SERGIO M. FOCARDI, PhD
Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: The principle of absence of arbitrage is perhaps the most fundamental principle of finance theory. In the presence of arbitrage opportunities, there is no trade-off between risk and returns because it is possible to make unbounded risk-free gains. The principle of absence of arbitrage is fundamental for understanding asset valuation in a competitive market. Arbitrage pricing can be developed in a finite-state, discrete-time setting and a continuous-time, continuous-state setting.

In this entry, we describe *arbitrage pricing* in the *continuous-state, continuous-time setting*. There are a number of important conceptual changes in going from a discrete-state, discrete-time setting (as described in the entry “Arbitrage Pricing: Finite-State Models”) to a continuous-state, continuous-time setting. First, each state of the world has probability zero. This precludes the use of standard conditional probabilities for the definition of conditional expectation and requires the use of filtrations (rather than of information structures) to describe the propagation of information. Second, the tools of matrix algebra are inadequate; the more complex tools of calculus and stochastic calculus are required. Third, simple generalizations are rarely possible as many pathological cases appear in connection with infinite sets.

THE ARBITRAGE PRINCIPLE IN CONTINUOUS TIME

Let’s start with the definition of basic concepts. The economy is represented by a probability space $(\Omega, \mathfrak{F}, P)$ where Ω is the set of possible states, \mathfrak{F} is the σ -algebra of events, and P is a probability measure. Time is a continuous variable in the interval $[0, T]$. The propagation of information is represented by a filtration \mathfrak{F}_t . The latter is a family of σ -algebras such that $\mathfrak{F}_t \subseteq \mathfrak{F}_s, t < s$.

Each security i is characterized by a payoff-rate process δ_t^i and by a price process S_t^i . In this continuous-state setting, δ_t^i and S_t^i are real variables with a continuous range such that $\delta_t^i(\omega)$ and $S_t^i(\omega)$ are, respectively, the payoff-rate and the price of the i -th asset at time $t, 0 \leq t \leq T$

and in state $\omega \in \Omega$. Note that δ_t^i represents a rate of payoff and not a payoff as was the case in the discrete-time setting. The payoff-rate process must be interpreted in the sense that the cumulative payoff of each individual asset is

$$D_t^i = \int_0^t \delta_s^i ds$$

We assume that the number of assets is finite. We can therefore use the vector notation to indicate a set of processes. For example, we write δ_t and S_t to indicate the vector process of payoff rates and prices respectively. All payoff-rates and prices are stochastic processes adapted to the filtration \mathfrak{F} . One can make assumptions about the price and the payoff-rate processes. For example, it can be assumed that price and payoff-rate processes satisfy a set of stochastic differential equations or that they exhibit finite jumps. Later in this entry we will explore a number of these processes.

Conditional expectations are defined as partial averaging. In fact, given a variable X_s , $s > t$, its conditional expectation $E_t[X_s]$ is defined as a variable that is \mathfrak{F}_t -measurable and whose average on each set $A \in \mathfrak{F}_t$ is the same as that of X :

$$Y_t = E_t[X_s] \Leftrightarrow E[Y_t(\omega)] = E[X_s(\omega)]$$

for $\omega \in A$, $\forall A \in \mathfrak{F}_t$ and Y is \mathfrak{F}_t -measurable.

The law of iterated expectations applies as in the finite-state case:

$$E_t[E_u(X_s)] = E_t[X_s]$$

In a continuous-state setting, conditional expectations are variables that assume constant values on the sets of infinite partitions. Imagine the evolution of a variable X . At the initial date, X_0 identifies the entire space Ω . At each subsequent date t , the space Ω is partitioned into an infinite number of sets, each determined by one of the infinite values of X_t .¹ However, these sets have measure zero. In fact, they are sets of the type: $\{A: \omega \in A \Leftrightarrow X_t(\omega) = x\}$ determined by specific values of the variable X_t . These sets

have probability zero as there is an infinite number of values X_t . As a consequence, we cannot define conditional expectation as expectation under the usual definition of conditional probabilities the same way we did in the case of finite-state setting.

Trading Strategies and Trading Gains

We have to define the meaning of trading strategies in the continuous-state, continuous-time setting; this requires the notion of continuous trading. Mathematically, continuous trading means that the composition of portfolios changes continuously at every instant and that these changes are associated with trading gains or losses. A trading strategy is a (vector-valued) process $\theta = \{\theta^i\}$ such that $\theta_t = \{\theta_t^i\}$ is the portfolio held at time t . To ensure that there is no anticipation of information, each trading strategy θ must be an adapted process.

Given a trading strategy, we have to define the gains or losses associated with it. In discrete time, the trading gains equal the sum of payoffs plus the change of a portfolio's value

$$\sum_{t=0}^T \left(\sum_t d_t^i \theta_t^i \right) + \sum_i S_T^i \theta_T^i - \sum_i S_0^i \theta_0^i$$

over a finite interval $[0, T]$.

We must define trading gains when time is a continuous variable. It is not possible to replace finite sums of stochastic increments with pathwise Riemann-Stieltjes integrals after letting the time interval go to zero. The reason is that, though we can assume that paths are continuous, we cannot assume that they have bounded variation. As a consequence, pathwise Riemann-Stieltjes integrals generally do not exist. However, we can assume that paths are of bounded quadratic variation. Under this latter assumption, using Itô isometry, we can define pathwise Itô integrals and stochastic integrals.

Let's first assume that the payoff-rate process is zero, so that there are only price processes. Under this assumption, the trading gain

T_t of a trading strategy can be represented by a stochastic integral:

$$T_t = \int_0^t \theta_s dS_s = \sum_i \int_0^t \theta_s^i dS_s^i$$

In the rest of this section, we will not strictly adhere to the vector notation when there is no risk of confusion. For example, we will write $\theta \cdot S$ to represent the scalar product $\theta \cdot S$. If a payoff-rate process is associated with each asset, we have to add the gains consequent to the payoff-rate process. We therefore define the gain process

$$G_t^i = S_t^i + D_t^i$$

as the sum of the price processes plus the cumulative payoff-rate processes, and we define the trading gains as the stochastic integral

$$T_t = \int_0^t \theta_s dG_s = \sum_i \int_0^t \theta_s^i dG_s^i$$

How can we match the abstract notion of a stochastic integral with the buying and selling of assets? In discrete time, trading gains have a meaning that is in agreement with the practical notion of buying a portfolio of assets, holding it for a period, and then selling it at market prices, thus realizing either a gain or a loss. One might object that in continuous time this meaning is lost. How can a process where prices change so that their total variation is unbounded be a reasonable representation of financial reality? This is a question of methodology that is relevant to every field of science. In classical physics, the use of continuous models was assumed to reflect reality; time and space, for example, were considered continuous. Quantum physics upset the conceptual cart of classical physics, and the reality of continuous processes has since been questioned at every level. In quantum physics, a theory is considered to be nothing but a model useful as a mathematical device to predict measurements. This is, in essence, the theory set forth in the 1930s by Niels Bohr and the school

of Copenhagen; it has now become mainstream methodology in physics. It is also, ultimately, the point of view of positive economics. In a famous and widely quoted essay, Milton Friedman (1953) wrote:

The relevant question to ask about the "assumptions" of a theory is not whether they are descriptively "realistic," for they never are, but whether they are sufficiently good approximations for the purpose in hand. And this question can be answered only by seeing whether the theory works, which means if it yields sufficiently accurate predictions.

In the spirit of positive economics, continuous-time financial models are mathematical devices used to predict, albeit in a probabilistic sense, financial observations made at discrete intervals of time. Stochastic gains predict trading gains only at discrete intervals of time—the only intervals that can be observed. Continuous-time finance should be seen as a logical construction that meets observations only at a finite number of dates, not as a realistic description of financial trading.

Let's consider processes without any intermediate payoff. A self-financing trading strategy is a trading strategy such that the following relationships hold:

$$\theta_t S_t = \sum_i \theta_t^i S_t^i = \sum_i \left(\theta_0^i S_0^i + \int_0^t \theta_t^i dS_t^i \right), t \in [0, T]$$

We first define arbitrage in the absence of a payoff-rate process. An arbitrage is a self-financing trading strategy such that: $\theta_0 S_0 < 0$ and $\theta_T S_T \geq 0$, or $\theta_0 S_0 \leq 0$ and $\theta_T S_T > 0$. If there is a payoff-rate process, a self-financing trading strategy is a trading strategy such that the following relationships hold:

$$\theta_t S_t = \sum_i \theta_t^i S_t^i = \sum_i \left(\theta_0^i S_0^i + \int_0^t \theta_t^i dG_t^i \right), t \in [0, T]$$

where $G_t^i = S_t^i + D_t^i$ is the gain process as previously defined. An arbitrage is a self-financing trading strategy such that: $\theta_0 S_0 < 0$ and $\theta_T S_T \geq 0$, or $\theta_0 S_0 \leq 0$ and $\theta_T S_T > 0$.

ARBITRAGE PRICING IN CONTINUOUS-STATE, CONTINUOUS-TIME

The abstract principles of arbitrage pricing are the same in a discrete-state, discrete-time setting as in a continuous-state, continuous-time setting. Arbitrage pricing is relative pricing. In the absence of arbitrage, the price and payoff-rate processes of a set of basic assets fix the prices of other assets given the payoff-rate process of the latter. If markets are complete, every price process can be computed in this way. In a discrete-state, discrete-time setting, the computation of arbitrage pricing is done with matrix algebra. In fact, in the absence of arbitrage, every price process can be expressed in two alternative ways:

1. Prices S_t^i are equal to the normalized conditional expectation of payoffs deflated with state prices under the real probabilities:

$$S_t^i = \frac{1}{\pi_t} E_t \left[\sum_{j=t+1}^T \pi_j d_j^i \right]$$

2. Prices S_t^i are equal to the conditional expectation of discounted payoffs under the risk-neutral probabilities

$$S_t^i = E_t^Q \left[\sum_{j=t+1}^T \frac{d_j^i}{R_{t,j}} \right]$$

State-price deflators and risk-neutral probabilities can be computed solving systems of linear equations for a kernel of basic assets. The above relationships are algebraic linear equations that fix all price processes.

In a continuous-state, continuous-time setting, the principle of arbitrage pricing is the same. In the absence of arbitrage, given a number of basic price and payoff stochastic processes, other processes are fixed. The latter are called *redundant securities* as they are not necessary to fix prices. If markets are complete, every price process can be fixed in this way. In

order to make computations feasible, some additional assumptions are made, in particular, all payoff-rate and price processes are assumed to be Itô processes.

The theory of arbitrage pricing in a continuous-state, continuous-time setting uses the same tools as in a discrete-state, discrete-time setting. Under an equivalent martingale measure, all price processes become martingales. Therefore prices can be determined as discounted present value relationships. *Equivalent martingale measures* are the same concept as state-price deflators: After appropriate deflation, all processes become martingales. The key point of arbitrage pricing theory is that both equivalent martingale measures and state-price deflators can be determined from a subset of the market. All other processes are redundant.

In the following sections we will develop the theory of arbitrage pricing in steps. First, we will illustrate the principles of arbitrage pricing in the case of options, arriving at the *Black-Scholes option pricing formula*. We will then extend this theory to more general derivative securities. Subsequently, we will state arbitrage pricing theory in the context of equivalent martingale measures and of state-price deflators.

OPTION PRICING

We will now apply the concepts of arbitrage pricing to option pricing in a continuous-state, continuous-time setting. Suppose that a market consists of three assets: a risk-free asset (which allows risk-free borrowing and lending at the risk-free rate of interest), a stock, and a European option. We will show that the price processes of a stock and of a risk-free asset fix the price process of an option on that stock.

Suppose the risk-free rate is a constant r . The value V_t of a risk-free asset with constant rate r evolves according to the deterministic differential equation of continually compounding interest rates:

$$dV_t = rV_t dt$$

The above is a differential equation with separable variables. After separating the variables, the equation can be written as

$$\frac{dV_t}{V_t} = r dt$$

which admits the solution $V_t = V_0 e^{rt}$ where V_0 is the initial value of the bank account. This formula can also be interpreted as the price process of a risk-free bond with deterministic rate r .

Stock Price Processes

Let's now examine the price process of the stock. Consider the process $y = \alpha t + \sigma B_t$ where B_t is a standard Brownian motion. From the definition of Itô integrals, it can be seen that this process, which is called an arithmetic Brownian motion, is the solution of the following diffusion equation:

$$dy_t = \alpha dt + \sigma dB_t$$

where α is a constant called the drift of the diffusion and σ is a constant called the *volatility of the diffusion*.

Consider now the process $S_t = S_0 e^{(\alpha t + \sigma B_t)}$, $t \geq 0$. Applying Itô's lemma it is easy to see that this process, which is called a geometric Brownian motion, is an Itô process that satisfies the following stochastic differential equation:

$$dS_t = \mu S_t dt + \sigma S_t dB_t; S_0 = x$$

where x is an initial value, $\mu = \alpha + 1/2\sigma^2$ and B_t is a standard Brownian motion. We assume that the stock price process follows a geometric Brownian motion and that there is no payoff-rate process.

Now consider a European call option, which gives the owner the right but not the obligation to buy the underlying stock at the exercise price K at the expiry date T . Call Y_t the price of the option at time t . The price of the option as a function of the stock price is known at the final

expiry date. If the option is rationally exercised, the final value of the option is

$$Y_T = \max(S_T - K, 0)$$

In fact, the option can be rationally exercised only if the price of the stock exceeds K . In that case, the owner of the option can buy the underlying stock at the price K , sell it immediately at the current price S_t and make a profit equal to $(S_t - K)$. If the stock price is below K , the option is clearly worthless. After T , the option ceases to exist.

How can we compute the option price at every other date? We can arrive at the solution in two different but equivalent ways: (1) through hedging arguments and (2) the equivalent martingale measures. In the following sections we will introduce hedging arguments and equivalent martingale measures.

Hedging

To hedge means to protect against an adverse movement. The seller of an option is subject to a liability as, from his point of view, the option has a negative payoff in some states. In our context, hedging this option means to form a self-financing trading strategy formed with the stock plus the risk-free asset in appropriate proportions such that the option plus this hedging portfolio is risk free. Hedging the option implies that the hedging portfolio perfectly replicates the option payoff in every possible state.

A European call option has only one payoff at the expiry date. It therefore suffices that the hedging portfolio replicates the option payoff at that date. Suppose that there is a self-financing trading strategy (θ_t^1, θ_t^2) in the bond and the stock such that

$$\theta_t^1 V_T + \theta_t^2 S_T = Y_T$$

To avoid arbitrage, the price of the option at any moment must be equal to the value of the hedging self-financing trading strategy. In fact, suppose that at any time $t < T$ the self-financing

strategy (θ_t^1, θ_t^2) has a value lower than the option:

$$\theta_t^1 V_t + \theta_t^2 S_t < Y_t$$

An investor could then sell the option for Y_t , make an investment $\theta_t^1 V_t + \theta_t^2 S_t$ in the trading strategy, and at time T liquidate both the option and the trading strategy. As $\theta_T^1 V_T + \theta_T^2 S_T = Y_T$ the final liquidation has value zero in every state of the world, so that the initial profit $Y_t - \theta_t^1 V_t + \theta_t^2 S_t$ is a risk-free profit. A similar reasoning could be applied if, at any time $t < T$, the strategy (θ_t^1, θ_t^2) had a value higher than the option. Therefore, we can conclude that if there is a self-financing trading strategy that replicates the option's payoff, the value of the strategy must coincide with the option's price at every instant prior to the expiry date.

Observe that the above reasoning is an instance of the law of one price. If two portfolios have the same payoffs at every moment and in every state of the world, their price must be the same. In particular, if a trading strategy has the same payoffs of an asset, its value must coincide with the price of that asset.

The Black-Scholes Option Pricing Formula

Let's now see how the price of the option can be computed. Assume that the price of the option is a function of time and of the price of the underlying stock: $Y_t = C(S_t, t)$. This assumption is reasonable but needs to be justified; for the moment it is only a hint as to how to proceed with the calculations. It will be justified later by verifying that the pricing formula produces the correct final payoff.

As S_t is assumed to be an Itô process, in particular a geometric Brownian motion, $Y_t = C(S_t, t)$ —which is a function of S_t —is an Itô process as well. Therefore, using Itô's formula, we can write down the stochastic equation that Y_t

must satisfy. Itô's formula prescribes that:

$$dY_t = \left[\frac{\partial C(S_t, t)}{\partial t} + \frac{\partial C(S_t, t)}{\partial S_t} S_t \mu + \frac{1}{2} \frac{\partial^2 C(S_t, t)}{\partial S_t^2} S_t^2 \sigma^2 \right] dt + \frac{\partial C(S_t, t)}{\partial S_t} \sigma S_t dB$$

Suppose now that there is a self-financing trading strategy $Y_t = \theta_t^1 V_t + \theta_t^2 S_t$. We can write this equation as

$$\int_0^t dY_t = \theta_t^1 \int_0^t dV_t + \theta_t^2 \int_0^t dS_t$$

or, in differential form, as

$$dY_t = \theta_t^1 dV_t + \theta_t^2 dS_t = (\theta_t^1 r V_t + \theta_t^2 \mu S_t) dt + \theta_t^2 \sigma S_t dB_t$$

If the trading strategy replicates the option price process, the two expressions for dY_t —the one obtained through Itô's lemma and the other obtained through the assumption that there is a replicating self-financing trading strategy—must be equal:

$$\begin{aligned} & (\theta_t^1 r V_t + \theta_t^2 \mu S_t) dt + \theta_t^2 \sigma S_t dB_t \\ &= \left[\frac{\partial C(S_t, t)}{\partial t} + \frac{\partial C(S_t, t)}{\partial S_t} S_t \mu + \frac{1}{2} \frac{\partial^2 C(S_t, t)}{\partial S_t^2} S_t^2 \sigma^2 \right] dt \\ &+ \frac{\partial C(S_t, t)}{\partial S_t} \sigma S_t dB_t \end{aligned}$$

The equality of these two expressions implies the equality of the coefficients in dt and dB respectively. Equating the coefficients in dB yields

$$\theta_t^2 = \frac{\partial C(S_t, t)}{\partial S_t}$$

As $Y_t = C(S_t, t) = \theta_t^1 V_t + \theta_t^2 S_t$, substituting, we obtain

$$\theta_t^1 = \frac{1}{V_t} \left[C(S_t, t) - \frac{\partial C(S_t, t)}{\partial S_t} S_t \right]$$

We have now obtained the self-financing trading strategy in function of the stock and option prices. Substituting and equating the

coefficients of dt yields

$$\begin{aligned} & \frac{1}{V_t} \left[C(S_t, t) - \frac{\partial C(S_t, t)}{\partial S_t} S_t \right] r V_t + \frac{\partial C(S_t, t)}{\partial S_t} \mu S_t \\ &= \frac{\partial C(S_t, t)}{\partial t} + \frac{\partial C(S_t, t)}{\partial S_t} S_t \mu + \frac{1}{2} \frac{\partial^2 C(S_t, t)}{\partial S_t^2} S_t^2 \sigma^2 \end{aligned}$$

Simplifying and eliminating common terms, we obtain

$$\begin{aligned} -rC(S_t, t) + r \frac{\partial C(S_t, t)}{\partial S_t} S_t + \frac{\partial C(S_t, t)}{\partial t} \\ + \frac{1}{2} \frac{\partial^2 C(S_t, t)}{\partial S_t^2} S_t^2 \sigma^2 = 0 \end{aligned}$$

If the function $C(S_t, t)$ satisfies this relationship, then the coefficients in dt match. The above relationship is a partial differential equation (PDE). This equation can be solved with suitable boundary conditions. Boundary conditions are provided by the payoff of the option at the expiry date:

$$Y_T = C(S_T, T) = \max(S_T - K, 0)$$

The closed-form solution of the above PDE with the above boundary conditions was derived by Black and Scholes (1973) and referred to as the *Black-Scholes option pricing formula*:

$$C(S_t, t) = x\Phi(z) - e^{-r(T-t)}K\Phi(z - \sigma\sqrt{T-t})$$

with

$$z = \frac{\log(S_t/K) + (r + \frac{1}{2}\sigma^2)(T-t)}{\sigma\sqrt{T-t}}$$

and where Φ is the cumulative normal distribution.

Let's stop for a moment and review the logical steps we have followed thus far. First, we defined a market made by a stock whose price process follows a geometric Brownian motion and a bond whose price process is a deterministic exponential. We introduced into this market a European call option. We then made two assumptions: (1) The option's price process is a deterministic function of the stock price process; and (2) the option's price process can be replicated by a self-financing trading strategy.

If the above assumptions are true, we can write a stochastic differential equation for the option's price process in two different ways: (1) Using Itô's lemma, we can write the option price stochastic process as a function of the stock stochastic process; and (2) using the assumption that there is a replicating trading strategy, we can write the option price stochastic process as the stochastic process of the trading process. As the two equations describe the same process, they must coincide. Equating the coefficients in the deterministic and stochastic terms, we can determine the trading strategy and write a deterministic PDE that the pricing function of the option must satisfy. The latter PDE together with the boundary conditions provided by the known value of the option at the expiry date uniquely determine the option pricing function.

Note that the above is neither a demonstration that there is an option pricing function, nor a demonstration that there is a replicating trading strategy. However, if both a pricing function and a replicating trading strategy exist, the above process allows one to determine both by solving a partial differential equation. After determining a solution to the PDE, one can verify if it provides a pricing function and if it allows the creation of a self-financing trading strategy. Ultimately, the justification of the existence of an option's pricing function and of a replicating self-financing trading strategy resides in the possibility of actually determining both. Absence of arbitrage ensures that this solution is unique.

Generalizing the Pricing of European Options

We can now generalize the above pricing methodology to a generic European option and to more general price processes for the bond and for the underlying stock. In the most general case, the process underlying a derivative need not be a stock price process. However, we

suppose that the underlying is a stock price process so that replicating portfolios can be formed. We generalize in three ways:

- The option's payoff is an arbitrary finite-variance random variable.
- The stock price process is an Itô process.
- The short-rate process is stochastic.

Following the definition given in the finite-state setting, we define a European option on some underlying process S_t as an asset whose payoff at time T is given by the random variable $Y_T = g(S_T)$ where $g(x)$, $x \in R$ is a continuous real-valued function. In other words, a European option is defined as a security whose payoff is determined at a given expiry date T as a function of some underlying random variable. The option has a zero payoff at every other date $t \in [0, T]$. This definition clearly distinguishes European options from American options, which yield payoffs at random stopping times.

Let's now generalize the price process of the underlying stock. We represent the underlying stock price process as a generic Itô process. A generic univariate Itô process can be represented through the differential stochastic equation:

$$dS_t = \mu(S_t, t)dt + \sigma(S_t, t)dB_t; S_0 = x$$

where x is the initial condition, B is a standard Brownian motion, and $\mu(S_t, t)$ and $\sigma(S_t, t)$ are given functions $R \times (0, \infty) \rightarrow R$. The geometric Brownian motion is a particular example of an Itô process.

Let's now define the bond price process. We retain the risk-free nature of the bond but let the interest rate be stochastic. Recall that in a discrete-state, discrete-time setting, a bond was defined as a process that, at each time step, exhibits the same return for each state though the return can be different in different time steps. Consequently, in continuous-time we define a bond price process as the following integral:

$$V_t = V_0 e^{\int_0^t r(S_u, u) du}$$

where r is a given function that represents the stochastic rate. In fact, the rate r depends on the time t and on the stock price process S_t . Application of Itô's lemma shows that the bond price process satisfies the following equation:

$$dV_t = V_t r(S_t, t) dt$$

We can now use the same reasoning that led to the Black-Scholes formula. Suppose that there are both an option pricing function $Y_t = C(S_t, t)$ and a replicating self-financing trading strategy

$$Y_t = \theta_t^1 V_t + \theta_t^2 S_t$$

We can now write a stochastic differential equation for the process Y_t in two ways:

- Applying Itô's lemma to $Y_t = C(S_t, t)$
- Directly to $Y_t = \theta_t^1 V_t + \theta_t^2 S_t$

The first approach yields

$$dY_t = \left[\frac{\partial C(S_t, t)}{\partial t} + \frac{\partial C(S_t, t)}{\partial S_t} \mu(S_t, t) + \frac{1}{2} \frac{\partial^2 C(S_t, t)}{\partial S_t^2} \sigma^2(S_t, t) \right] dt + \frac{\partial C(S_t, t)}{\partial S_t} \sigma(S_t, t) dB_t$$

The second approach yields

$$dY_t = [\theta_t^1 r(S_t, t) V_t + \theta_t^2 \mu(S_t, t)] dt + \theta_t^2 \sigma(S_t, t) dB_t$$

Equating coefficients in dt, dB we obtain the trading strategy

$$\theta_t^1 = \frac{1}{V_t} \left[C(S_t, t) - \frac{\partial C(S_t, t)}{\partial S_t} S_t \right]$$

$$\theta_t^2 = \frac{\partial C(S_t, t)}{\partial S_t}$$

and the PDE

$$-r(x, t)C(x, t) + r(x, t) \frac{\partial C(x, t)}{\partial x} x + \frac{\partial C(x, t)}{\partial t} + \frac{1}{2} \frac{\partial^2 C(x, t)}{\partial x^2} \sigma^2(x, t) = 0$$

with the boundary conditions $C(S_T, T) = g(S_T)$. Solving this equation we obtain a candidate option pricing function. In each specific case, one

can then verify that the option pricing function effectively solves the option pricing problem.

STATE-PRICE DEFLATORS

We now extend the concepts of state prices and equivalent martingale measures to a continuous-state, continuous-time setting. As in the previous sections, the economy is represented by a probability space $(\Omega, \mathfrak{F}, P)$ where Ω is the set of possible states, \mathfrak{F} is the σ -algebra of events, and P is a probability measure. Time is a continuous variable in the interval $[0, T]$. The propagation of information is represented by a filtration \mathfrak{F}_t . A multivariate standard Brownian motion $B = (B_1, \dots, B_D)$ in R^D adapted to the filtration \mathfrak{F}_t is defined over this probability space. We know that there are mathematical subtleties that we will not take into consideration, as regards whether (1) the filtration is given and the Brownian motion is adapted to the filtration or (2) the filtration is generated by the Brownian motion.

Suppose that there are N price processes $\mathbf{X} = (X^1, \dots, X^N)$ that form a multivariate Itô process in R^N . Trading strategies are adapted processes $\theta = (\theta^1, \dots, \theta^N)$ that represent the quantity of each asset held at each instant. In order to ensure the existence of stochastic integrals, we require the processes (X^1, \dots, X^N) and any trading strategy to be of bounded variation. Let's first suppose that there is no payoff-rate process. This assumption will be relaxed in a later section. Suppose also that one of these processes, say X_t^1 , is defined by a short-rate process r , so that

$$X_t^1 = e^{\int_0^t r_u du}$$

or

$$dX_t^1 = r_t X_t^1 dt$$

where r_t is a deterministic function of t called the short-rate process. Note that X_t^1 could be replaced by a trading strategy. We can think of r_t as the risk-free short-term continuously compounding interest rate and of X_t^1

as a risk-free continuously compounding bank account.

The concept of arbitrage and of trading strategy was defined in the previous section. We now introduce the concept of deflators in a continuous-time continuous-state setting. Any strictly positive Itô process is called a *deflator*. Given a deflator Y we can deflate any process X , obtaining a new deflated process

$$X_t^Y = X_t Y_t$$

For example, any stock price process of a non-defaulting firm or the risk-free bank account is a deflator. For technical reasons it is necessary to introduce the concept of regular deflators. A *regular deflator* is a deflator that, after deflation, leaves unchanged the set of admissible bounded-variation trading strategies.

We can make the first step towards defining a theory of pricing based on equivalent martingale measures. It can be demonstrated that if Y is a regular deflator, a trading strategy θ is self-financing with respect to the price process $\mathbf{X} = (X^1, \dots, X^N)$ if and only if it is self-financing with respect to the deflated price process

$$\mathbf{X}^Y = (Y_t X_t^1, \dots, Y_t X_t^N)$$

In addition, it can be demonstrated that the price process $\mathbf{X} = (X^1, \dots, X^N)$ admits no arbitrage if and only if the deflated price process

$$\mathbf{X}^Y = (Y_t X_t^1, \dots, Y_t X_t^N)$$

admits no arbitrage.

A *state-price deflator* is a deflator π with the property that the deflated price process \mathbf{X}^π is a martingale. A martingale is a stochastic process M_t such that its current value equals the conditional expectation of the process at any future time: $M_t = E_t[M_s]$, $s > t$. For each price process X_t^i , the following relationship therefore holds:

$$\pi_t X_t^i = E_t[\pi_s X_s^i], s > t$$

This definition is the equivalent in continuous time of the definition of a state-price deflator in discrete time. In fact, a state-price deflator is

defined as a process π such that

$$S_t^i = \frac{1}{\pi_t} E_t \left[\sum_{j=t+1}^T \pi_j d_j^i \right]$$

If there is no intermediate payoff, as in our present case, the previous relationship can be written as

$$\begin{aligned} \pi_t S_t^i &= E_t[\pi_T S_T^i] = E_t[E_{t+1}[\pi_T S_T^i]] \\ &= E_t[\pi_{t+1} S_{t+1}^i] \end{aligned}$$

The next proposition states that if there is a regular state-price deflator, then there is no arbitrage. The demonstration of this proposition hinges on the fact that, as the deflated price process is a martingale, the following relationship holds:

$$E \left[\int_0^T \theta_u dS_u^\pi \right] = 0$$

and therefore any self-financing trading strategy is a martingale. We can thus write

$$\theta_0 S_0^\pi = E[\theta_T S_T^\pi]$$

If

$$\begin{aligned} \theta_T S_T^\pi \geq 0 \quad \text{then} \quad \theta_0 S_0^\pi \geq 0 \\ \text{and if} \quad \theta_T S_T^\pi > 0 \quad \text{then} \quad \theta_0 S_0^\pi > 0 \end{aligned}$$

which shows that there cannot be any arbitrage.

We have now stated that the existence of state-price deflators ensures the absence of arbitrage. The converse of this statement in a continuous-state, continuous-time setting is more delicate and will be dealt with later. We will now move on to equivalent martingale measures.

EQUIVALENT MARTINGALE MEASURES

In the previous section we saw that if there is a regular state-price deflator then there is no arbitrage. A state-price deflator transforms every price process and every self-financing trading strategy into a martingale. We will now see that,

after discounting by an appropriate process, price processes become martingales through a transformation of the real probability measure into an equivalent martingale measure.² This theory parallels the theory of equivalent martingale measures developed in the discrete-state, discrete-time setting in the entry "Arbitrage Pricing: Finite-State Models." First some definitions must be discussed.

Given a probability measure P , the probability measure Q is said to be equivalent to P if both assign probability zero to the same events, that is, if $P(A) = 0$ if and only if $Q(A) = 0$ for every event A . The equivalent probability measure Q is said to be an *equivalent martingale measure* for the process X if X is a martingale with respect to Q and if the Radon-Nikodym derivative

$$\xi = \frac{dQ}{dP}$$

has finite variance. The definition of the Radon-Nikodym derivative is the same here as it is in the finite-state context. The Radon-Nikodym derivative is a random variable ξ such that $Q(A) = E^P[\xi I_A]$ for every event A where I_A is the indicator function of the event A .

To develop an intuition for this definition, consider that any stochastic process X is a time-dependent random variable X_t . The latter is a family of functions $\Omega \rightarrow R$ from the set of states to the real numbers indexed with time such that the sets $\{X_t(\omega) \leq x\}$ are events for any real x . Given the probability measure P , the finite-dimension distributions of the process X are determined. The equivalent measure Q determines another set of finite-dimension distributions. However, the correspondence between the process paths and the states remains unchanged.

The requirement that P and Q are equivalent is necessary to ensure that the process is effectively the same under the two measures. There is no assurance that given an arbitrary process an equivalent martingale measure exists. Let's assume that an equivalent martingale measure does exist for the N -dimensional price process

$\mathbf{X} = (X^1, \dots, X^N)$. It can be demonstrated that if the price process $\mathbf{X} = (X^1, \dots, X^N)$ admits an equivalent martingale measure, then there is no arbitrage.

The proof is similar to that for state-price deflators as discussed above. Under the equivalent martingale measure Q , which we assume exists, every price process and every self-financing trading strategy becomes a martingale. Using the same reasoning as above it is easy to see that there is no arbitrage.

This result can be generalized; here is how. If there is a regular deflator Y such that the deflated price process $\mathbf{X}^Y = (Y_t X_t^1, \dots, Y_t X_t^N)$ admits an equivalent martingale measure, then there is no arbitrage. The proof hinges on the result established in the previous section that, if there is a regular deflator Y , the price process \mathbf{X} admits no arbitrage if and only if the deflated price process \mathbf{X}^Y admits no arbitrage.

Note that none of these results is constructive. They only state that the existence of an equivalent martingale measure with respect to a price process ensures the absence of arbitrage. Conditions to ensure the existence of an equivalent martingale measure with respect to a price process are given in the next section.

EQUIVALENT MARTINGALE MEASURES AND GIRSANOV'S THEOREM

We first need to establish an important mathematical result known as *Girsanov's theorem*. This theorem applies to Itô processes. Let's first state Girsanov's theorem in simple cases. Let X be a single-valued Itô process where B is a single-valued standard Brownian motion:

$$X_t = x + \int_0^t \mu_s ds + \int_0^t \sigma_s dB_s$$

Suppose that a process v and a process θ such that $\sigma_t \theta_t = \mu_t - v_t$ are given. Suppose, in addition, that the process θ satisfies the Novikov

condition which requires

$$E \left[e^{\left(\frac{1}{2} \int_0^t \theta_s^2 ds \right)} \right] < \infty$$

Then, there is a probability measure Q equivalent to P such that the following integral

$$\hat{B}_t = B_t + \int_0^t \theta_s ds$$

defines a standard Brownian motion \hat{B}_t in R on $(\Omega, \mathfrak{F}, Q)$ with the same standard filtration of the original Brownian motion B_t . In addition, under Q the process X becomes

$$X_t = x + \int_0^t v_s ds + \int_0^t \sigma_s d\hat{B}_s$$

Girsanov's theorem states that we can add drift to a standard Brownian motion and still obtain a standard Brownian motion under another probability measure. In addition, by changing the probability measure we can arbitrarily change the drift of an Itô process.

The same theorem can be stated in multiple dimensions. Let X be an N -valued Itô process:

$$X_t = x + \int_0^t \mu_s ds + \int_0^t \sigma_s dB_s$$

In this process, μ_s is an N -vector process and σ_s is an $N \times D$ matrix. Suppose that there are both a vector process $v = (v^1, \dots, v^N)$ and a vector process $\theta = (\theta^1, \dots, \theta^N)$ such that $\sigma_t \theta_t = \mu_t - v_t$ where the product $\sigma_t \theta_t$ is not a scalar product but is performed component by component. Suppose, in addition, that the process θ satisfies the Novikov condition:

$$E \left[e^{\left(\frac{1}{2} \int_0^t \theta \cdot \theta ds \right)} \right] < \infty$$

Then there is a probability measure Q equivalent to P such that the following integral

$$\hat{B}_t = B_t + \int_0^t \theta_s ds$$

defines a standard Brownian motion \hat{B}_t in R^D on $(\Omega, \mathfrak{F}, Q)$ with the same standard filtration of the original Brownian motion B_t . In addition, under Q the process X becomes

$$X_t = x + \int_0^t v_s ds + \int_0^t \sigma_s d\hat{B}_s$$

Girsanov's theorem essentially states that under technical conditions (the Novikov condition) by changing the probability measure, it is possible to transform an Itô process into another Itô process with arbitrary drift. Prima facie, this result might seem unreasonable. In the end the drift of a process seems to be a fundamental feature of the process as it defines, for example, the average of the process. Consider, however, that a stochastic process can be thought as the set of all its possible paths. In the case of an Itô process, we can identify the process with the set of all continuous and square integrable functions. As observed above, the drift is an average, and it is determined by the probability measure on which the process is defined. Therefore, it should not be surprising that by changing the probability measure it is possible to change the drift.

The Diffusion Invariance Principle

Note that Girsanov's theorem requires neither that the process X be a martingale nor that Q be an equivalent martingale measure. If X is indeed a martingale under Q , an implication of Girsanov's theorem is the diffusion invariance principle, which can be stated as follows. Let X be an Itô process:

$$dX_t = \mu_t dt + \sigma_t dB_t$$

If X is a martingale with respect to an equivalent probability measure Q , then there is a standard Brownian motion \hat{B}_T in R^D under Q such that

$$dX_t = \sigma_t d\hat{B}_t$$

Let's now apply the previous results to a price process $X = (V, S^1, \dots, S^{N-1})$ where

$$dS_t = \mu_t dt + \sigma_t dB_t$$

and

$$dV_t = r_t V_t dt$$

If the short-term rate r is bounded, V_t^{-1} is a regular deflator. Consider the deflated processes:

$$Z_t = S_t V_t^{-1}$$

By Itô's lemma, this process satisfies the following stochastic equation:

$$dZ_t = \left(-r_t Z_t + \frac{\mu_t}{V_t} \right) dt + \frac{\sigma_t}{V_t} dB_t$$

Suppose there is an equivalent martingale measure Q . Under the equivalent martingale measure Q , the discounted price process

$$Z_t = S_t V_t^{-1}$$

is a martingale. In addition, by the diffusion invariance principle there is a standard Brownian motion \hat{B}_t in R^D under Q such that:

$$dZ_t = \frac{\sigma_t}{V_t} d\hat{B}_t$$

Applying Itô's lemma, given that $Z_t V_t = S_t$, we obtain the fundamental result:

$$dS_t = r_t dt + \sigma_t d\hat{B}_t$$

This result states that, under the equivalent martingale measure, all price processes become Itô processes with the same drift.

Application of Girsanov's Theorem to Black-Scholes Option Pricing Formula

To illustrate Girsanov's theorem, let's see how the Black-Scholes option pricing formula can be obtained from an equivalent martingale measure. In the previous setting, let's assume that $N = 3$, $d = 1$, r_t is a constant and

$$\sigma_t = \sigma S_t$$

with σ constant. Let S be the stock price process and C be the option price process. The option's price at time T is

$$C = \max(S_T^1 - K)$$

In this setting, therefore, the following three equations hold:

$$\begin{aligned} dS_t &= \mu_t^S dt + \sigma S_t^S dB_t \\ dC_t^2 &= \mu_t^C dt + \sigma_t^C dB_t \\ dV_t &= rV_t dt \end{aligned}$$

Given that $C_t V_t^{-1}$ is a martingale, we can write

$$C_t = V_t E_t^Q \left[\frac{C_T^2}{V_t} \right] = E_t^Q [e^{-r(T-t)} \max(S_T - K)]$$

It can be demonstrated by direct computation that the above formula is equal to the Black-Scholes option pricing formula presented earlier in this entry.

EQUIVALENT MARTINGALE MEASURES AND COMPLETE MARKETS

In the continuous-state, continuous-time setting, a market is said to be complete if any finite-variance random variable Y can be obtained as the terminal value at time T of a self-financing trading strategy θ : $Y = \theta_T X_T$. A fundamental theorem of arbitrage pricing states that, in the absence of arbitrage, a market is complete if and only if there is a unique equivalent martingale measure. This condition can be made more specific given that the market is populated with assets that follow Itô processes. Suppose that the price process is $\mathbf{X} = (V, S^1, \dots, S^{N-1})$ where, as in the previous section:

$$\begin{aligned} dS_t &= \mu_t dt + \sigma_t dB_t \\ dV_t &= rV_t dt \end{aligned}$$

and \mathbf{B} is a standard Brownian motion $B = (B^1, \dots, B^D)$ in R^D .

It can be demonstrated that markets are complete if and only if $\text{rank}(\sigma) = d$ almost everywhere. This condition should be compared with

the conditions for completeness we established in the discrete-state setting. In that setting, we demonstrated that markets are complete if and only if the number of linearly independent price processes is equal to the maximum number of branches leaving a node. In fact, market completeness is equivalent to the possibility of solving a linear system with as many equations as branches leaving each node.

In the present continuous-state setting, there are infinite states and so we need different types of considerations. Roughly speaking, each price process (which is an Itô process) depends on D independent sources of uncertainty as we assume that the standard Brownian motion is D -dimensional. In a finite-state setting this means that, if processes are Markovian, at each time step any process can jump to D different values. The market is complete if there are D independent price processes. Note that the number D is arbitrary.

EQUIVALENT MARTINGALE MEASURES AND STATE PRICES

We will now show that equivalent martingale measures and state prices are the same concept. We use the same setting as in the previous sections. Suppose that Q is an equivalent martingale measure after deflation by the process

$$\frac{1}{V_t^1} = e^{\int_0^t -r_u du}$$

where r is a bounded short-rate process. The density process ξ_t for Q is defined as

$$\xi_t = E_r \left[\frac{dQ}{dP} \right], t \in [0, T]$$

where

$$\left[\frac{dQ}{dP} \right]$$

is the Radon-Nikodym derivative of Q with respect to P . As in the discrete-state setting, the Radon-Nikodym derivative of Q with respect

to P is a random variable

$$\xi = \left[\frac{dQ}{dP} \right]$$

with average value on the entire space equal to 1 and such that, for every event A , the probability of A under Q is the average of ξ :

$$P^Q(A) = E_A[\xi]$$

It can be demonstrated that, given any \mathfrak{F}_t -measurable random variable W , the density process ξ_t for Q has the following property:

$$E_t^Q[W] = \frac{E_t[W\xi_t]}{\xi_t}$$

To gain an intuition for the Radon-Nikodym derivative in a continuous-state setting, let's assume that the probability space is the real line equipped with the Borel σ -algebra and with a probability measure P . In this case, $\xi = \xi(x)$, $R \rightarrow R$ and we can write

$$Q(A) = \int_A \xi dP$$

or, $dQ = \xi dP$. Given any random variable X with density f under P and density q under Q , we can then write

$$E^Q[X] = \int_R xq(x)dx = \int_R x\xi(x)f(x)dx$$

In other words, the random variable ξ is a function that multiplies the density f to yield the density q .

We can now show the following key result. Given an equivalent martingale measure with density process ξ_t a state-price deflator is given by the process

$$\pi_t = \xi_t e^{\int_0^t -r_u du}$$

Conversely, given a state-price deflator π_t , the density process

$$\xi_t = e^{\int_0^t r_u du} \frac{\pi_t}{\pi_0}$$

defines an equivalent martingale measure. In fact, suppose that Q is an equivalent martingale

measure for X^Y with $\pi_t = \xi_t Y_t$ where

$$Y_t = e^{\int_0^t -r_u du}$$

Then, using the above relationship we can write:

$$\begin{aligned} E_t[\pi_t X_t] &= E_t[\xi_t X_t^Y] = \xi_t E_t^Q[\xi_t X_t^Y] = \xi_t X_t^Y \\ &= \pi_t X_t \end{aligned}$$

which shows that π_t is a state-price deflator. The same reasoning in reverse order demonstrates that if π_t is a state-price deflator then:

$$\xi_t = e^{\int_0^t r_u du} \frac{\pi_t}{\pi_0}$$

is a density process for Q .

ARBITRAGE PRICING WITH A PAYOFF RATE

In the analysis thus far, we assumed that there is no intermediate payoff. The owner of an asset makes a profit or a loss due only to the changes in value of the asset. Let's now introduce a payoff-rate process δ_t^i for each asset i . The payoff-rate process must be interpreted in the sense that the cumulative payoff of each individual asset is

$$D_t^i = \int_0^t \delta_s^i ds$$

We define a gain process

$$G_t^i = S_t^i + D_t^i$$

By the linearity of the Itô integrals, we can write any trading strategy as

$$\int_0^t \theta_t dG_t = \int_0^t \theta_t dX_t + \int_0^t \theta_t dD_t$$

If there is a payoff-rate process, a self-financing trading strategy is a trading strategy

such that the following relationship holds:

$$\theta_t \mathbf{S}_t = \sum_i \theta_t^i S_t^i = \sum_i \left(\theta_t^i S_t^i + \int_0^t \theta_t^i dG_t^i \right), t \in [0, T]$$

An arbitrage is, as before, a self-financing trading strategy such that

$$\theta_0 \mathbf{S}_0 < 0 \text{ and } \theta_T \mathbf{S}_T \geq 0, \text{ or } \theta_0 \mathbf{S}_0 \leq 0 \text{ and } \theta_T \mathbf{S}_T > 0$$

The previous arguments extend to this case. An equivalent martingale measure for the pair (D, S) is defined as an equivalent probability measure Q such that the Radon-Nikodym derivative

$$\xi = \left[\frac{dQ}{dP} \right]$$

has finite variance and the process $G = S + D$ is a martingale. Under these conditions, the following relationship holds:

$$S_t = E_t^Q \left[e^{\int_t^T -r_u du} + \int_t^T e^{\int_t^s -r_u du} dD_s \right]$$

IMPLICATIONS OF THE ABSENCE OF ARBITRAGE

We saw that the existence of an equivalent martingale measure or of state-price deflators implies absence of arbitrage. We have also seen that, in the absence of arbitrage, markets are complete if and only if there is a unique equivalent martingale measure.

In a discrete-state, discrete-time context we could establish the complete equivalence between the existence of state-price deflators, equivalent martingale measures and absence of arbitrage, in the sense that any of these conditions implies the other two. In addition, the existence of a unique equivalent martingale measure implies absence of arbitrage and market completeness.

In the present continuous-state context, however, absence of arbitrage implies the existence

of an equivalent martingale measure and of state price deflators only under rather restrictive and complex technical conditions. If we want to relax these conditions, the condition of absence of arbitrage has to be slightly modified. These discussions are quite technical and will not be presented in this entry.³

WORKING WITH EQUIVALENT MARTINGALE MEASURES

The concepts established in the preceding sections of this entry might seem very complex, abstract, and scarcely useful. On the contrary, they entail important simplifications in the computation of derivative prices. Applications of these computations can be found in the pricing of bonds and credit derivatives. Here we want to make a few general comments on how these tools are used.

The key result of the arbitrage pricing theory is that, under the equivalent martingale measure, all discounted price processes become martingales and all price processes have the same drift. Therefore, all calculations can be performed under the assumption that the change to an equivalent martingale measure has been made. This environment allows important simplifications. For example, as we have seen, the option pricing problem becomes a problem of computing the present value of simpler processes.

Obviously one has to go back to a real environment at the end of the pricing exercise. This is essentially a calibration problem, as risk-neutral probabilities have to be estimated from real probabilities. Despite this complication, the equivalent martingale methodology has proved to be an important tool in derivative pricing.

KEY POINTS

- A trading strategy is a vector-valued process that represents portfolio weights at each moment.

- Trading gains are defined as stochastic integrals.
- A self-financing trading strategy is one whose value at every moment is the initial value plus the trading gains at that moment.
- An arbitrage is a self-financing trading strategy whose initial value is either negative and the final value nonnegative or the initial value non-negative and the final value positive.
- The Black-Scholes option pricing formula can be established by replicating self-financing trading strategies.
- The Black-Scholes pricing argument is based on constructing a self-financing trading strategy that replicates the option price in each state and for each time.
- Absence of arbitrage implies that a replicating self-financing trading strategy must have the same price as the option.
- The Black-Scholes option pricing formula is obtained by solving the partial differential equation implied by the equality of the replicating self-financing trading strategy and the option price process.
- A deflator is any strictly positive Itô process; a state-price deflator is a deflator with the property that the deflated price process is a martingale.
- If there is a (regular) state-price deflator, then there is no arbitrage; the converse is true only under a number of technical conditions.
- Two probability measures are said to be equivalent if they assign probability zero to the same event.
- Given a process X on a probability space with probability measure P , the probability measure Q is said to be an equivalent martingale measure if it is equivalent to P and X is a martingale with respect to Q (plus other conditions).
- If there is a regular deflator such that the deflated price process admits an equivalent martingale measure, then there is no arbitrage.
- Under the equivalent martingale measure, all Itô price processes have the same drift.
- In the absence of arbitrage, a market is complete if and only if there is a unique equivalent martingale measure.

NOTES

1. One can visualize this process as a tree structure with an infinite number of branches and an infinite number of branching points. However, as the number of branches and of branching points is a continuum, intuition might be misleading.
2. The theory of equivalent martingale measures was developed in Harrison and Pliska (1981, 1985) and Harrison and Kreps (1979).
3. See Delbaen and Schachermayer (1994, 1999).

Abstract: One of the basic mechanisms of learning is assimilating the information arriving from the external environment and then updating the existing knowledge base with that information. This mechanism lies at the heart of the Bayesian framework. A Bayesian decision maker learns by revising beliefs in light of the new data that become available. From the Bayesian point of view, probabilities are interpreted as degrees of belief. Therefore, the Bayesian learning process consists of revising probabilities. Contrast this with the way probability is interpreted in the classical (frequentist) statistical theory—as the relative frequency of occurrence of an event in the limit, as the number of observations goes to infinity. Bayes' theorem provides the formal means of putting that mechanism into action; it is a simple expression combining the knowledge about the distribution of the model parameters and the information about the parameters contained in the data.

Quantitative financial models describe in mathematical terms the relationships between financial random variables through time and/or across assets. The fundamental assumption is that the model relationship is valid independent of the time period or the asset class under consideration. Financial data contain both meaningful information and random noise. An adequate financial model not only extracts optimally the relevant information from the his-

torical data but also performs well when tested with new data. The uncertainty brought about by the presence of data noise makes imperative the use of statistical analysis as part of the process of financial model building, model evaluation, and model testing.

Statistical analysis is employed from the vantage point of either of the two main statistical philosophical traditions—frequentist and Bayesian. An important difference between the

two lies with the interpretation of the concept of probability. As the name suggests, advocates of frequentist statistics adopt a *frequentist* interpretation: The probability of an event is the limit of its long-run relative frequency (i.e., the frequency with which it occurs as the amount of data increases without bound). Strict adherence to this interpretation is not always possible in practice. When studying rare events, for instance, large samples of data may not be available and in such cases proponents of frequentist statistics resort to theoretical results. The Bayesian view of the world is based on the subjectivist interpretation of probability: Probability is subjective, a degree of belief that is updated as information or data are acquired.

The concept of subjective probability is derived from arguments for rationality of the preferences of agents. It originated in the 1930s with the (independent) works of Bruno de Finetti (1931) and Frank Ramsey (1931), and was further developed by Leonard Savage (1954) and Dennis Lindley (1971). The subjective probability interpretation can be traced back to the Scottish philosopher and economist David Hume, who also had philosophical influence over Harry Markowitz (by Markowitz's own words in his autobiography published in *Les Prix Nobel*, 1991).

Closely related to the concept of probability is that of uncertainty. Proponents of the frequentist approach consider the source of uncertainty to be the randomness inherent in realizations of a random variable. The probability distributions of variables are not subject to uncertainty. In contrast, Bayesian statistics treats probability distributions as uncertain and subject to modification as new information becomes available. Uncertainty is implicitly incorporated by probability updating. The probability beliefs based on the existing knowledge base take the form of the *prior probability*.

The *posterior probability* represents the updated beliefs. Since the beginning of the last century, when quantitative methods and models became a mainstream tool to aid in un-

derstanding financial markets and formulating investment strategies, the framework applied in finance has been the frequentist approach. The term *frequentist* usually refers to the Fisherian philosophical approach named after Sir Ronald Fisher.

Strictly speaking, "Fisherian" has a broader meaning as it includes not only frequentist statistical concepts such as unbiased estimators, hypothesis tests, and confidence intervals, but also the maximum likelihood estimation framework pioneered by Fisher. Only in the last two decades has Bayesian statistics started to gain greater acceptance in financial modeling, despite its introduction about 250 years ago by Thomas Bayes, a British minister and mathematician. It has been the advancements of computing power and the development of new computational methods that has fostered the growing use of Bayesian statistics in finance.

On the applicability of the Bayesian conceptual framework, consider an excerpt from the speech of the former chairman of the Board of Governors of the Federal Reserve System, Alan Greenspan, at the Meeting of the American Statistical Association in San Diego, California, January 3, 2004:

The Federal Reserve's experiences over the past two decades make it clear that uncertainty is not just a pervasive feature of the monetary policy landscape; it is the defining characteristic of that landscape. The term "uncertainty" is meant here to encompass both "Knightian uncertainty," in which the probability distribution of outcomes is unknown, and "risk," in which uncertainty of outcomes is delimited by a known probability distribution. . . . This conceptual framework emphasizes understanding as much as possible the many sources of risk and uncertainty that policymakers face, quantifying those risks when possible, and assessing the costs associated with each of the risks. In essence, the risk management approach to monetary policymaking is an application of Bayesian [decision making].

The three steps of Bayesian decision making that Alan Greenspan outlines are:

1. Formulating the prior probabilities to reflect existing information.

2. Constructing the quantitative model, taking care to incorporate the uncertainty intrinsic in model assumptions.
3. Selecting and evaluating a utility function describing how uncertainty affects alternative model decisions.

While these steps constitute the rigorous approach to Bayesian decision making, applications of Bayesian methods to financial modeling often only involve the first two steps or even only the second step. This tendency is a reflection of the pragmatic Bayesian approach that financial modelers often favor.

Applications of the *Bayesian framework* to financial modeling include:

- Bayesian approach to mean-variance portfolio selection.
- Reflecting degrees of belief in an asset pricing model when selecting an optimal portfolio.
- Bayesian methods of portfolio selection within the context of the Black-Litterman model.
- Computing measures of market efficiency.
- Estimating complex volatility models.

All of these applications are presented in Rachev et al. (2008).

In this entry, we discuss some of the basic principles of Bayesian analysis.

THE LIKELIHOOD FUNCTION

Suppose we are interested in analyzing the returns on a given stock and have available a historical record of returns. Any analysis of these returns, beyond a very basic one, would require that we make an educated guess about (propose) a process that might have generated these return data. Assume that we have decided on some statistical distribution and denote it by

$$p(y|\theta) \quad (1)$$

where y is a realization of the random variable Y (stock return) and θ is a parameter specific to

the distribution, p . Assuming that the distribution we proposed is the one that generated the observed data, we draw a conclusion about the value of θ . Obviously, central to that goal is our ability to summarize the information contained in the data. The likelihood function is a statistical construct with this precise role. Denote the n observed stock returns by y_1, y_2, \dots, y_n . The joint density function of Y , for a given value of θ , is

$$f(y_1, y_2, \dots, y_n | \theta)$$

By using the term “density function,” we implicitly assume that the distribution chosen for the stock return is continuous, which is invariably the case in financial modeling.

We can observe that the function above can also be treated as a function of the unknown parameter, θ , given the observed stock returns. That function of θ is called the *likelihood function*. We write it as

$$L(\theta | y_1, y_2, \dots, y_n) = f(y_1, y_2, \dots, y_n | \theta) \quad (2)$$

Suppose we have determined from the data two competing values of θ , θ_1 and θ_2 , and want to determine which one is more likely to be the true value (at least, which one is closer to the true value). The likelihood function helps us make that decision. Assuming that our data were indeed generated by the distribution in (1), θ_1 is more likely than θ_2 to be the true parameter value whenever $L(\theta_1 | y_1, y_2, \dots, y_n) > L(\theta_2 | y_1, y_2, \dots, y_n)$. This observation provides the intuition behind the method most often employed in “classical” statistical inference to estimate θ from the data alone—the *method of maximum likelihood*. The value of θ most likely to have yielded the observed sample of stock return data, y_1, y_2, \dots, y_n , is the maximum likelihood estimate, $\hat{\theta}$, obtained from maximizing the likelihood function in (2).

To illustrate the concept of a likelihood function, we briefly discuss two examples—one based on the Poisson distribution (a discrete

distribution) and another based on the normal distribution (one of the most commonly employed continuous distributions).

The Poisson Distribution Likelihood Function

The Poisson distribution is often used to describe the random number of events occurring within a certain period of time. It has a single parameter, θ , indicating the rate of occurrence of the random event, that is, how many events happen on average per unit of time. The probability distribution of a Poisson random variable, X , is described by the following expression:

$$p(X = k) = \frac{\theta^k}{k!} e^{-\theta}, \quad k = 0, 1, 2, \dots \quad (3)$$

The Poisson distribution is employed in the context of finance (most often, but not exclusively, in the areas of credit risk and operational risk) as the distribution of a stochastic process, called the Poisson process, which governs the occurrences of random events.

Suppose we are interested in examining the annual number of defaults of North American corporate bond issuers and we have gathered a sample of data for the period from 1986 through 2005. Assume that these corporate defaults occur according to a Poisson distribution. Denoting the 20 observations by x_1, x_2, \dots, x_{20} , we write the likelihood function for the Poisson parameter θ (the average rate of defaults) as¹

$$\begin{aligned} L(\theta | x_1, x_2, \dots, x_{20}) &= \prod_{i=1}^{20} p(X = x_i | \theta) = \prod_{i=1}^{20} \frac{\theta^{x_i}}{x_i!} e^{-\theta} \\ &= \frac{\theta^{\sum_{i=1}^{20} x_i}}{\prod_{i=1}^{20} x_i!} e^{-20\theta} \end{aligned} \quad (4)$$

It is often customary to retain in the expressions for the likelihood function and the probability distributions only the terms that contain the unknown parameter(s); that is, we get rid of the terms that are constant with respect to the pa-

rameter(s). Thus, (4) could be written as

$$L(\theta | x_1, x_2, \dots, x_{20}) \propto \theta^{\sum_{i=1}^{20} x_i} e^{-20\theta} \quad (5)$$

where \propto denotes “proportional to.” Clearly, for a given sample of data, the expressions in (4) and (5) are proportional to each other and therefore contain the same information about θ . Maximizing either of them with respect to θ , we obtain that the maximum likelihood estimator of the Poisson parameter, θ , is the sample mean, \bar{x} :

$$\hat{\theta} = \bar{x} = \frac{\sum_{i=1}^{20} x_i}{20}$$

For the 20 observations of annual corporate defaults, we get a sample mean of 51.6. The Poisson probability distribution function (evaluated at θ equal to its maximum-likelihood estimate, $\hat{\theta} = 51.6$) and the likelihood function for θ can be visualized, respectively, in the left-hand-side and right-hand-side plots in Figure 1.

The Normal Distribution Likelihood Function

The normal distribution (also called the Gaussian distribution) has been the predominant distribution of choice in finance because of the relative ease of dealing with it and the availability of attractive theoretical results resting on it.² It is certainly one of the most important distributions in statistics. Two parameters describe the normal distribution—the location parameter, μ , which is also its mean, and the scale (dispersion) parameter, σ , also called standard deviation. The probability density function of a normally distributed random variable Y is expressed as

$$f(y) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(y-\mu)^2}{2\sigma^2}} \quad (6)$$

where y and μ could take any real value and σ can only take positive values. We denote the distribution of Y by $Y \sim N(\mu, \sigma)$. The normal density is symmetric around the mean, μ , and its plot resembles a bell.

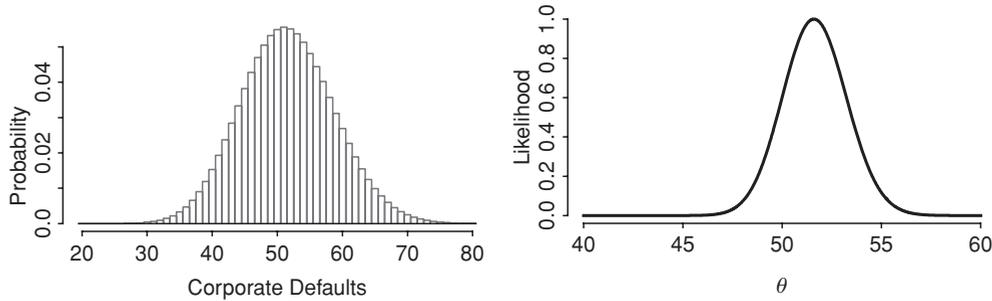

Figure 1 The Poisson Distribution Function and Likelihood Function

Note: The graph on the left represents the mass function of the Poisson random variable evaluated at the maximum-likelihood estimate, $\hat{\theta} = 51.6$. The graph on the right represents the likelihood function for the parameter of the Poisson distribution.

Suppose we have gathered daily dollar return data on the MSCI-Germany Index for the period January 2, 1998, through December 31, 2003 (a total of 1,548 returns), and we assume that the daily return is normally distributed. Then, given the realized index returns (denoted by $y_1, y_2, \dots, y_{1548}$), the likelihood function for the parameters μ and σ is written in the following way:

$$\begin{aligned}
 L(\mu, \sigma \mid y_1, y_2, \dots, y_{1548}) &= \prod_{i=1}^{1548} f(y_i) \\
 &= \left(\frac{1}{\sqrt{2\pi}\sigma} \right)^{1548} e^{-\sum_{i=1}^{1548} \frac{(y_i - \mu)^2}{2\sigma^2}} \\
 &\propto \sigma^{-1548} e^{-\sum_{i=1}^{1548} \frac{(y_i - \mu)^2}{2\sigma^2}} \quad (7)
 \end{aligned}$$

We again implicitly assume that the MSCI-Germany index returns are independently and identically distributed (IID), that is, each daily return is a realization from a normal distribution with the same mean and standard deviation.

In the case of the normal distribution, since the likelihood is a function of two arguments, we can visualize it with a three-dimensional surface as in Figure 2. It is also useful to plot the so-called contours of the likelihood, which we obtain by “slicing” the shape in Figure 2 horizontally at various levels of the likelihood.

Each contour corresponds to a pair of parameter values (and the respective likelihood value). In Figure 3, for example, we could observe that the pair $(\mu, \sigma) = (-0.23e - 3, 0.31e - 3)$, with a likelihood value of 0.6, is more likely than the pair $(\mu, \sigma) = (0.096e - 3, 0.33e - 3)$, with a likelihood value of 0.1, since the corresponding likelihood is larger.

BAYES' THEOREM

Bayes' theorem is the cornerstone of the Bayesian framework. Formally, it is a result from introductory probability theory, linking the unconditional distribution of a random variable with its conditional distribution. For Bayesian

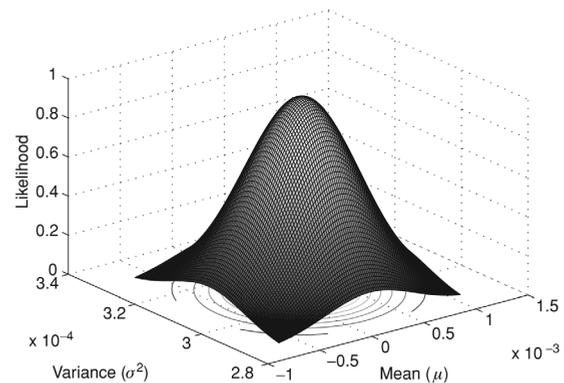

Figure 2 The Likelihood Function for the Parameters of the Normal Distribution

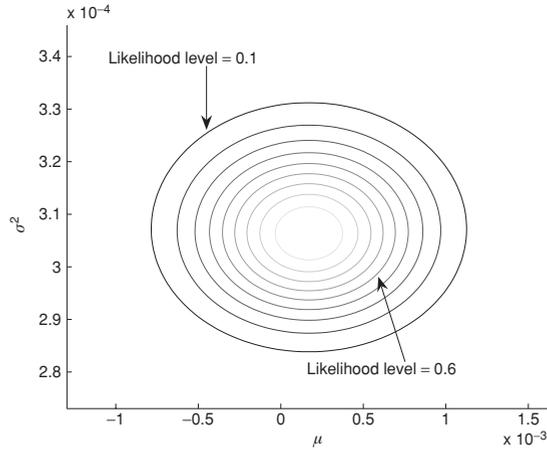

Figure 3 The Likelihood Function for the Parameters of the Normal Distribution: Contour Plot

proponents, it is the representation of the philosophical principle underlying the Bayesian framework that probability is a measure of the degree of belief one has about an uncertain event. Bayes' theorem is a rule that can be used to update the beliefs that one holds in light of new information (for example, observed data).

We first consider the discrete version of Bayes' theorem. Denote the evidence prior to observing the data by E and suppose that a researcher's belief in it can be expressed as the probability $P(E)$. The Bayes theorem tells us that, after observing the data, D , the belief in E is adjusted according to the following expression:

$$P(E | D) = \frac{P(D | E) \times P(E)}{P(D)} \quad (8)$$

where:

1. $P(D | E)$ is the conditional probability of the data given that the prior evidence, E , is true.
2. $P(D)$ is the unconditional (marginal) probability of the data, $P(D) > 0$; that is, the probability of D irrespective of E , also expressed as

$$P(D) = P(D | E) \times P(E) + P(D | E^c) \times P(E^c)$$

where the subscript c denotes a complementary event.³

The probability of E before seeing the data, $P(E)$, is called the *prior probability*, whereas the updated probability, $P(E | D)$, is called the *posterior probability*.⁴ Notice that the magnitude of the adjustment of the prior probability, $P(E)$, after observing the data is given by the ratio $P(D|E)/P(D)$. The conditional probability, $P(D|E)$, when considered as a function of E , is in fact the likelihood function, as will become clear further below.

As an illustration, consider a manager in an event-driven hedge fund. The manager is testing a strategy that involves identifying potential acquisition targets and examines the effectiveness of various company screens, in particular the ratio of stock price to free cash flow per share (PFCF). Let us define the following events:

D = Company X 's PFCF has been more than three times lower than the sector average for the past three years.

E = Company X becomes an acquisition target in the course of a given year.

Independently of the screen, the manager assesses the probability of company X being targeted at 40%. That is, denoting by E^c the event that X does not become a target in the course of the year, we have

$$P(E) = 0.4$$

and

$$P(E^c) = 0.6$$

Suppose further that the manager's analysis suggests that the probability a target company's PFCF has been more than three times lower than the sector average for the past three years is 75% while the probability that a nontarget company has been having that low of a PFCF for the past three years is 35%:

$$P(D | E) = 0.75$$

and

$$P(D | E^c) = 0.35$$

If a bidder does appear on the scene, what is the chance that the targeted company had been detected by the manager's screen? To answer this question, the manager needs to update the prior probability $P(E)$ and compute the posterior probability $P(E | D)$. Applying (8), we obtain

$$P(E | D) = \frac{0.75 \times 0.4}{0.75 \times 0.4 + 0.35 \times 0.6} \approx 0.59 \quad (9)$$

After taking into account the company's persistently low PFCF, the probability of a takeover increases from 40% to 59%.

In financial applications, the continuous version of the Bayes' theorem (as follows later) is predominantly used. Nevertheless, the discrete form has some important uses, two of which we briefly outline now.

Bayes' Theorem and Model Selection

The usual approach to modeling of a financial phenomenon is to specify the analytical and distributional properties of a process that one thinks generated the observed data and treat this process as if it were the true one. Clearly, in doing so, one introduces a certain amount of error into the estimation process. Accounting for model risk might be no less important than accounting for (within-model) parameter uncertainty, although it seems to preoccupy researchers less often.

One usually entertains a small number of models as plausible ones. The idea of applying the Bayes' theorem to model selection is to combine the information derived from the data with the prior beliefs one has about the degree of model validity. One can then select the single "best" model with the highest posterior probability and rely on the inference provided by it or one can weigh the inference of each model by its posterior probability and obtain an "averaged-out" conclusion.

Bayes' Theorem and Classification

Classification refers to assigning an object, based on its characteristics, into one out of several categories. It is most often applied in the area of credit and insurance risk, when a creditor (an insurer) attempts to determine the creditworthiness (riskiness) of a potential borrower (policyholder). Classification is a statistical problem because of the existence of information asymmetry—the creditor's (insurer's) aim is to determine with very high probability the unknown status of the borrower (policyholder). For example, suppose that a bank would like to rate a borrower into one of three categories: low risk (L), medium risk (M), and high risk (H). It collects data on the borrower's characteristics such as the current ratio, the debt-to-equity ratio, the interest coverage ratio, and the return on capital. Denote these observed data by the four-dimensional vector \mathbf{y} . The dynamics of \mathbf{y} depends on the borrower's category and is described by one of three (multivariate) distributions,

$$f(\mathbf{y} | C = L) \\ f(\mathbf{y} | C = M)$$

or

$$f(\mathbf{y} | C = H)$$

where C is a random variable describing the category. Let the bank's belief about the borrower's category be π_i , where

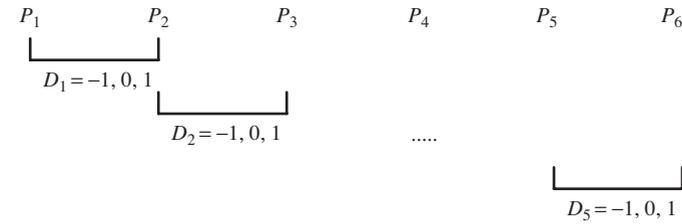

$$\pi_1 = \pi(C = L) \\ \pi_2 = \pi(C = M)$$

and

$$\pi_3 = \pi(C = H)$$

The discrete version of Bayes' theorem can be employed to evaluate the posterior (updated) probability, $\pi(C = i | \mathbf{y})$, $i = L, M, H$, that the borrower belongs to each of the three categories.

Let us now take our first steps in illustrating how Bayes' theorem helps in making inferences about an unknown distribution parameter.

where $D_i = -1$ if $P_{i+1} < P_i$
 $D_i = 0$ if $P_{i+1} = P_i$
 $D_i = 1$ if $P_{i+1} > P_i$

$$A_1 = D_1 + D_2$$

$$A_2 = D_2 + D_3$$

...

$$A_4 = D_4 + D_5$$

Note: X = number of occurrences of $A = 2$ within the sample period

Figure 4 The Number of Consecutive Trade-by-Trade Price Increases

Bayesian Inference for the Binomial Probability

Suppose we are interested in analyzing the dynamic properties of the intraday price changes for a stock. In particular, we want to evaluate the probability of consecutive trade-by-trade price increases. In an oversimplified scenario, this problem could be formalized as a binomial experiment.

The binomial experiment is a setting in which the source of randomness is a binary one (only takes on two alternative modes/states) and the probability of both states is constant throughout. The binomial random variable is the number of occurrences of the state of interest. In our illustration, the two states are “the consecutive trade-by-trade price change is an increase” and “the consecutive trade-by-trade price change is a decrease or null.” The random variable is the number of consecutive price increases. Denote it by X . Denote the probability of a consecutive increase by θ . Our goal is to draw a conclusion about the unknown probability, θ .

As an illustration, we consider the transaction data for the AT&T stock during the two-month period from January 4, 1993, through February

26, 1993 (a total of 55,668 price records). The diagram in Figure 4 shows how we define the binomial random variable given six price observations, P_1, \dots, P_6 . (Notice that the realizations of the random variable are one less than the number of price records.) A consecutive price increase is “encoded” as $A = 2$ and its probability is $\theta = P(A = 2)$; all other realizations of A ($A = -2, -1, 0$ or 1) have a probability of $1 - \theta$. We say that the number of consecutive price increases, X , is distributed as a binomial random variable with parameter θ . The probability mass function of X is represented by the expression

$$P(X = x | \theta) = \binom{n}{x} \theta^x (1 - \theta)^{n-x} \quad x = 0, 1, 2, \dots, n \quad (10)$$

where n is the sample size (the number of trade-by-trade price changes; a price change could be zero) and $\binom{n}{x} = \frac{n!}{x!(n-x)!}$. During the sample period, there are $X = 176$ trade-by-trade consecutive price increases. This information is embodied in the likelihood function for θ :

$$L(\theta | X = 176) = \theta^{176} (1 - \theta)^{55667-176} \quad (11)$$

We would like to combine that information with our prior belief about what the probability of a consecutive price increase is. We denote the prior distribution of an unknown parameter θ by $\pi(\theta)$, the posterior distribution of θ by $\pi(\theta | \text{data})$, and the likelihood function by $L(\theta | \text{data})$.

We consider two prior scenarios for the probability of consecutive price increases, θ :

1. We do not have any particular belief about the probability θ . Then, the prior distribution could be represented by a uniform distribution on the interval $[0, 1]$. Note that this prior assumption implies an expected value for θ of 0.5. The density function of θ is given by

$$\pi(\theta) = 1, \quad 0 \leq \theta \leq 1$$

2. Our intuition suggests that the probability of a consecutive price increase is around 2%. A possible choice of a prior distribution for θ is the beta distribution.⁵ The density function of θ is then written as

$$\pi(\theta | \alpha, \beta) = \frac{1}{B(\alpha, \beta)} \theta^{\alpha-1} (1 - \theta)^{\beta-1}, \quad 0 \leq \theta \leq 1 \tag{12}$$

where $\alpha > 0$ and $\beta > 0$ are the parameters of the beta distribution and $B(\alpha, \beta)$ is the so-called beta function. We set the parameters α and β to 1.6 and 78.4, respectively.

Figure 5 presents the plots of the two prior densities. Notice that under the uniform prior, all values of θ are equally likely, while under the beta prior, we assert higher prior probability for some values and lower prior probability for others.

Combining the sample information with the prior beliefs, we obtain θ 's posterior distribution. We rewrite Bayes' theorem with the notation in the current discussion:

$$p(\theta | x) = \frac{L(\theta | x)\pi(\theta)}{f(x)} \tag{13}$$

where $f(x)$ is the unconditional (marginal) distribution of the random variable X , given by

$$f(x) = \int L(\theta | x)\pi(x) d\theta \tag{14}$$

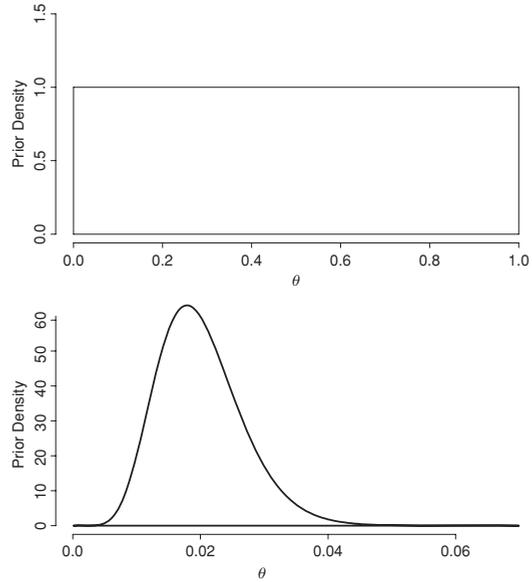

Figure 5 Density Curves of the Two Prior Distributions for the Binomial Parameter, θ
 Note: The density curve on top is the uniform density, while the one at the bottom is the beta density.

Since $f(x)$ is obtained by averaging over all possible values of θ , it does not depend on θ . Therefore, we can rewrite (8) as

$$\pi(\theta | x) \propto L(\theta | x)\pi(\theta) \tag{15}$$

The expression in (15) provides us with the posterior density of θ up to some unknown constant. However, in certain cases we would still be able to recognize the posterior distribution as a known distribution, as we see shortly.⁶ Since both assumed prior distributions of θ are continuous, the posterior density is also continuous and (13) and (15), in fact, represent the *continuous version of Bayes' theorem*.

Let us see what the posterior distribution for θ is under each of the two prior scenarios.

1. The posterior of θ under the uniform prior scenario is written as

$$\begin{aligned} \pi(\theta | x) &\propto L(\theta | x) \times 1 \\ &\propto \theta^{176} (1 - \theta)^{55667-176} \\ &= \theta^{177-1} (1 - \theta)^{55492-1} \end{aligned} \tag{16}$$

where the first α refers to omitting the marginal data distribution term in (14), while the second α refers to omitting the constant term from the likelihood function.

The expression $\theta^{177-1}(1-\theta)^{55492-1}$ above resembles the density function of the beta distribution in (12). The missing part is the term $B(177, 55492)$, which is a constant with respect to θ . We call $\theta^{\alpha-1}(1-\theta)^{\beta-1}$ the kernel of a beta distribution with parameters α and β . Obtaining it is sufficient to identify uniquely the posterior of θ as a beta distribution with parameters $\alpha = 177$ and $\beta = 55492$.

- The beta distribution is the conjugate prior distribution for the binomial parameter θ . This means that the posterior distribution of θ is also a beta distribution (of course, with updated parameters):

$$\begin{aligned}\pi(\theta | x) &\propto L(\theta | x)\pi(\theta) \\ &\propto \theta^{176}(1-\theta)^{55667-176}\theta^{1.6-1}(1-\theta)^{78.4-1} \\ &= \theta^{177.6-1}(1-\theta)^{55569.4-1}\end{aligned}\quad (17)$$

where again we omit any constants with respect to θ . As expected, we can recognize the expression in the last line above as the kernel of a beta distribution with parameters $\alpha = 177.6$ and $\beta = 55569.4$.

Finally, we might want to obtain a single number as an estimate of θ . In the classical (frequentist) setting, the usual estimator of θ is the maximum likelihood estimator (the value maximizing the likelihood function in (11)), which happens to be the sample proportion $\hat{\theta}$:

$$\hat{\theta} = \frac{176}{55667} = 0.00316 \quad (18)$$

or 0.316%.

In the Bayesian setting, one possible estimate of θ is the *posterior mean*, that is, the mean of θ 's posterior distribution. Since the mean of the beta distribution is given by $\alpha/(\alpha + \beta)$, the posterior mean of θ (the expected probability of consecutive trade-by-trade increase in the price of the AT&T stock) under the uniform prior

scenario is

$$\tilde{\theta}_U = \frac{177}{177 + 55492} = 0.00318$$

or 0.318%, while the posterior mean of θ under the beta prior scenario is

$$\tilde{\theta}_B = \frac{177.6}{177.6 + 55569.4} = 0.00319$$

or 0.319%.

The two posterior estimates and the maximum-likelihood estimate are the same for all practical purposes. The reason is that the sample size is so large that the information contained in the data sample “swamps out” the prior information.

KEY POINTS

- Statistical analysis is employed from the vantage point of either of the two main statistical philosophical traditions—frequentist and Bayesian.
- The frequentist interpretation of the probability of an event is that it is the limit of its long-run relative frequency (i.e., the frequency with which it occurs as the amount of data increases without bound).
- The Bayesian view of the world is based on the subjectivist interpretation of probability: Probability is subjective, a degree of belief that is updated as information or data are acquired.
- In the Bayesian framework, probability beliefs based on the existing knowledge base take the form of the prior probability; the posterior probability represents the updated beliefs.
- The likelihood function is a statistical construct summarizing the information contained in the sample of data.
- Bayes' theorem links the unconditional and unconditional probabilities. Under the Bayesian approach, prior beliefs are combined with sample information to create updated posterior beliefs.

- Two important applications of the discrete form of Bayes' theorem are model selection and classification.
- In financial applications, the continuous version of Bayes' theorem is predominantly used.

NOTES

1. In this example, we assume, perhaps unrealistically, that θ stays constant through time and that the annual number of defaults in a given year is independent from the number of defaults in any other year within the 20-year period. The independence assumption means that each observation of the number of annual defaults is regarded as a realization from a Poisson distribution with the same average rate of defaults, θ ; this allows us to represent the likelihood function as the product of the mass function at each observation.
2. One such result is the Central Limit Theorem which asserts that, under certain mild regularity conditions, sums of independent random variables are distributed with the normal distribution asymptotically (as the terms of the sum become indefinitely many).
3. The complement (complementary event) of E , E_c , includes all possible outcomes that could occur if E is not realized. The probabilities of an event and its complement always sum up to 1: $P(E) + P(E_c) = 1$.
4. The expression in (8) is easily generalized to the case when a researcher updates be-

liefs about one of many mutually exclusive events (such that two or more of them occur at the same time). Denote these events by E_1, E_2, \dots, E_K . The events are such that their probabilities sum up to 1: $P(E_1) + \dots + P(E_K) = 1$. Bayes' theorem then takes the form

$$P(E_k | D) = \frac{P(D | E_k) \times P(E_k)}{P(D | E_1) \times P(E_1) + P(D | E_2) \times P(E_2) + \dots + P(D | E_K) \times P(E_K)}$$

for $k = 1, \dots, K$ and $P(D) > 0$.

5. The beta distribution is the conjugate distribution for the parameter of the binomial distribution.
6. When the posterior distribution is not recognizable as a known distribution, inference about θ is accomplished with the help of numerical methods.

Abstract: Bayesian inference is the process of arriving at estimates of the model parameters reflecting the blending of information from different sources. Most commonly, two sources of information are considered: prior knowledge or beliefs and observed data. The discrepancy (or lack thereof) between them and their relative strength determines how far away the resulting Bayesian estimate is from the corresponding classical estimate. Along with the point estimate, which most often is the posterior mean, in the Bayesian setting one has available the whole posterior distribution, allowing for a richer analysis.

In this entry, we focus on the essentials of *Bayesian inference*. Formalizing the practitioner's knowledge and intuition into prior distributions is a key part of the inferential process. Especially when the data records are not abundant, the choice of prior distributions can influence greatly posterior conclusions. After presenting an overview of some approaches to prior specification, we focus on the elements of posterior analysis. Posterior and predictive results can be summarized in a few numbers, as in the classical statistical approach, but one

could also easily examine and draw conclusions about all other aspects of the posterior and predictive distributions of the (functions of the) parameters.

PRIOR INFORMATION

The prior distribution for the model parameters is an integral component of the Bayesian inference process. The updated (posterior) beliefs are the result of the trade-off between the prior

and data distributions. The continuous form of Bayes' theorem is:

$$p(\theta | \mathbf{y}) \propto L(\theta | \mathbf{y})\pi(\theta) \quad (1)$$

where

θ = unknown parameter whose inference we are interested in.

\mathbf{y} = a vector (or a matrix) of recorded observations.

$\pi(\theta)$ = prior distribution of θ depending on one or more parameters, called *hyperparameters*.

$L(\theta | \mathbf{y})$ = likelihood function for θ .

$p(\theta | \mathbf{y})$ = posterior (updated) distribution of θ .

Two factors determine the degree of posterior trade-off—the strength of the prior information and the amount of data available. Generally, unless the prior is very informative (in a sense that will become clear), the more observations, the greater the influence of the data on the posterior distribution. On the contrary, when very few data records are available, the prior distribution plays a predominant role in the updated beliefs.

How to translate the prior information about a parameter into the analytical (distributional) form, $\pi(\theta)$, and how sensitive the posterior inference is to the choice of prior have been questions of considerable interest in the Bayesian literature.¹ There is, unfortunately, no “best” way to specify the prior distribution and translating subjective views into prior values for the distribution parameters could be a difficult undertaking.

Before we review some commonly used approaches to prior elicitation, we make the following notational and conceptual note. It is often convenient to represent the posterior distribution, $p(\theta | \mathbf{y})$, in a logarithmic form. Then, it is easy to see that the expression in (1) is transformed according to

$$\log(p(\theta | \mathbf{y})) = \text{const} + \log(L(\theta | \mathbf{y})) + \log(\pi(\theta)),$$

where const is the logarithm of the constant of proportionality.

Informative Prior Elicitation

Prior beliefs are informative when they modify substantially the information contained in the data sample so that the conclusions we draw about the model parameters based on the posterior distribution and on the data distribution alone differ. The most commonly used approach to representing informative prior beliefs is to select a distribution for the unknown parameter and specify the hyperparameters so as to reflect these beliefs.

Informative Prior Elicitation for Location and Scale Parameters

Usually, when we think about the average value that a random variable takes, we have the typical value in mind. Therefore, we hold beliefs about the median of the distribution rather than its mean.² This distinction does not matter in the case of symmetric distributions, since then the mean and the median coincide. However, when the distribution we selected is not symmetric, care must be taken to ensure that the prior parameter values reflect our beliefs. Formulating beliefs about the spread of the distribution is less intuitive. The easiest way to do so is to ask ourselves questions such as, for instance: Which value of the random variable do a quarter of the observations fall below/above? Denoting the random variable by X , the answers to these questions give us the following probability statements:

$$P(X < x_{0.25}) = 0.25$$

and

$$P(X > x_{0.75}) = 0.25$$

where $x_{0.25}$ and $x_{0.75}$ are the values we have subjectively determined and are referred to as the first and third quartiles of the distribution, respectively. Other similar probability statements

can be formulated, depending on the prior beliefs.

As an example, suppose that we model the behavior of the monthly returns on some financial asset and the normal distribution, $N(\mu, \sigma^2)$ (along with the assumption that the returns are independently and identically distributed), describes their dynamics well. Assume for now that the variance is known, $\sigma^2 = \sigma^{2*}$, and thus we only need to specify a prior distribution for the unknown mean parameter, μ . We believe that a symmetric distribution is an appropriate choice and go for the simplicity of a normal prior:

$$\mu \sim N(\eta, \tau^2) \quad (2)$$

where η is the prior mean and τ^2 is the prior variance of μ ; to fully specify μ 's prior, we need to (subjectively) determine their values. We believe that the typical monthly return is around 1%, suggesting that the median of μ 's distribution is 1%. Therefore, we set η to 1%. Further, suppose we (subjectively) estimate that there is about a 25% chance that the average monthly return is less than 0.5% (i.e., $\mu_{0.25} = 0.5\%$). Then, using the tabulated cumulative probability values of the standard normal distribution, we find that the implied variance, τ^2 , is approximately equal to 0.74^2 .³ Our choice for the prior distribution of μ is thus $\pi(\mu) = N(1, 0.74^2)$.

Noninformative Prior Distributions

In many cases, our prior beliefs are vague and thus difficult to translate into an informative prior. We therefore want to reflect our uncertainty about the model parameter(s) without substantially influencing the posterior parameter inference. The so-called *noninformative priors*, also called vague or diffuse priors, are employed to that end.

Most often, the noninformative prior is chosen to be either a uniform (flat) density defined on the support of the parameter or the *Jeffreys' prior*.⁴ The noninformative distribution for a location parameter, μ , is given by a uniform

distribution on its support $((-\infty, \infty))$, that is,⁵

$$\pi(\mu) \propto 1 \quad (3)$$

The noninformative distribution for a scale parameter, σ (defined on the interval $(0, \infty)$) is⁶

$$\pi(\sigma) \propto \frac{1}{\sigma} \quad (4)$$

Notice that the prior densities in both (3) and (4) are not proper densities, in the sense that they do not integrate to one:

$$\int_{-\infty}^{\infty} 1 \, d\mu = \infty$$

and

$$\int_0^{\infty} \frac{1}{\sigma} \, d\sigma = \infty$$

Even though the resulting posterior densities are usually proper, care must be taken to ensure that this is indeed the case. To avoid impropriety of the posterior distributions, one could employ proper prior distributions but make them noninformative, as we discuss further on.

When one is interested in the joint posterior inferences for μ and σ , these two parameters are often assumed independent, giving the joint prior distribution

$$\pi(\mu, \sigma) \propto \frac{1}{\sigma} \quad (5)$$

The prior in (5) is often referred to as the *Jeffreys' prior*.⁷

Prior ignorance could also be represented by a (proper) standard distribution with a very large dispersion—the so-called flat or diffuse proper prior distribution. Let us turn again to the example for the monthly returns for some financial asset we considered earlier and suppose that we do not have particular prior information about the range of typical values the mean monthly return could take. To reflect this ignorance, we might center the normal distribution of μ around 0 (a neutral value, so to speak) and fix the standard deviation, τ , at a large value such as 10^6 , that is, $\pi(\mu) = N(0, (10^6)^2)$.

The prior of μ could take alternative distributional forms. For instance, a symmetric

Student's t -distribution could be asserted. A standard Student's t -distribution has a single parameter, the degrees of freedom, ν , which one can use to regulate the heaviness of the prior's tails—the lower ν is, the flatter the prior distribution. Asserting a scaled Student's t -distribution with a scale parameter, σ , provides additional flexibility in specifying the prior of μ .⁸ It can be argued that eliciting heavy-tailed prior distributions (with tails heavier than the tails of the data distribution) increases the posterior's robustness, that is, lowers the sensitivity of the posterior to the prior specification.

Conjugate Prior Distributions

In many situations, the choice of a prior distribution is governed by the desire to obtain analytically tractable and convenient posterior distribution. Thus, if one assumes that the data have been generated by a certain class of distributions, employing the class of the so-called "conjugate prior distributions" guarantees that the posterior distribution is of the same class as the prior distribution.⁹ Although the prior and posterior distributions have the same form, their parameters differ—the parameters of the posterior distribution reflects the trade-off between prior and sample information. We now consider the case of the normal data distribution, since it is central to our discussions of financial applications.

If the data, x , are assumed to come from a normal distribution, the conjugate priors for the normal mean, μ , and variance, σ^2 , are, respectively, a normal distribution and an inverted χ^2 distribution¹⁰

$$\pi(\mu | \sigma^2) = N\left(\eta, \frac{\sigma^2}{T}\right)$$

and

$$\pi(\sigma^2) = \text{Inv} - \chi^2(\nu_0, c_0^2) \quad (6)$$

where $\text{Inv} - \chi^2(\nu, c^2)$ denotes the inverted χ^2 distribution with ν_0 degrees of freedom and a scale parameter c_0^2 . The prior parameters (hyperparameters) that need to be (subjectively)

specified in advance are η , T , ν_0 , and c_0^2 . The parameter T plays the role of a discount factor, reflecting the degree of uncertainty about the distribution of μ . Usually, T is greater than one since one naturally holds less uncertainty about the distribution of the mean, μ , (with variance σ^2/T) than the data, x (with variance σ^2).

In various financial applications, the normal distribution is often not the most appropriate assumption for a data-generation process in view of various empirical features that financial data exhibit. Alternative distributional choices most often do not have corresponding conjugate priors and the resulting posterior distributions might not be recognizable as any known distributions. Then, numerical methods are applied to compute the posteriors.

In general, eliciting conjugate priors should be preceded by an analysis of whether prior beliefs would be adequately represented by them.

Empirical Bayesian Analysis

So far, we took care to emphasize the subjective manner in which prior information is translated into a prior distribution. This involves specifying the prior hyperparameters (if an informative prior is asserted) before observing/analyzing the set of data used for model evaluation. One approach for eliciting the hyperparameters parts with this tradition—the so-called "empirical Bayesian approach." In it, sample information is used to compute the values of the hyperparameters. Here we provide an example with the natural conjugate prior for a normal data distribution.

Denote the sample of n observations by $x = (x_1, x_2, \dots, x_n)$. It can be shown that the normal likelihood function can be expressed in the following way:

$$\begin{aligned} L(\mu, \sigma^2 | x) &= (2\pi\sigma^2)^{-n/2} \exp\left(-\frac{\sum_{i=1}^n (x_i - \mu)^2}{2\sigma^2}\right) \\ &= (2\pi\sigma^2)^{-n/2} \exp\left(-\frac{1}{2\sigma^2} (\nu s^2 + n(\mu - \hat{\mu})^2)\right) \end{aligned} \quad (7)$$

where

$$\begin{aligned}\hat{\mu} &= \frac{\sum_{i=1}^n x_i}{n}, \quad v = n - 1, \\ \text{and} \\ s^2 &= \frac{\sum_{i=1}^n (x_i - \hat{\mu})^2}{n - 1}\end{aligned}\quad (8)$$

The quantities $\hat{\mu}$ and s^2 are, respectively, the unbiased estimators of the mean, μ , and the variance, σ^2 , of the normal distribution.¹¹ It is now easy to see that the likelihood in (7) can be viewed as the product of two distributions—a normal distribution for μ conditional on σ^2 ,

$$\mu | \sigma \sim N\left(\hat{\mu}, \frac{\sigma^2}{n}\right)$$

and an inverted χ^2 distribution for σ^2 ,

$$\sigma^2 \sim \text{Inv} - \chi^2(v, s^2)$$

which become the prior distributions under the empirical Bayesian approach. We can observe that these two distributions are, of course, the same as the ones in (6). Their parameters are functions of the two sufficient statistics for the normal distribution, instead of subjectively elicited quantities. The sample size, n , above plays the role of the discount factor, T , in (6)—the more data available, the less uncertain one is about the prior distribution of μ (its prior variance decreases).

We now turn to a discussion of the fundamentals of posterior inference. Later in this entry, we provide an illustration of the effect various prior assumptions have on the posterior distribution.

POSTERIOR INFERENCE

The posterior distribution of a parameter (vector) θ given the observed data \mathbf{x} is denoted as $p(\theta | \mathbf{x})$ and obtained by applying the Bayes' theorem given by (1). Being a combination of the data and the prior, the posterior contains all relevant information about the unknown parameter θ .

Posterior Point Estimates

Although the benefit of being able to visualize the whole posterior distribution is unquestionable, it is often more practical to report several numerical characteristics describing the posterior, especially if reporting the results to an audience used to the classical (frequentist) statistical tradition. Commonly used for this purpose are the point estimates, such as the posterior mean, the posterior median, and the posterior standard deviation.¹² When the posterior is available in closed form, these numerical summaries can also be expressed in closed form. The posterior parameters in the natural conjugate prior scenario with a normal sampling density (see (6)) are also available analytically. The mean parameter, μ , of the normal distribution has a normal posterior, conditional on σ^2 ,

$$p(\mu | \mathbf{x}, \sigma^2) = N\left(\mu^*, \frac{\sigma^2}{T + n}\right) \quad (9)$$

The posterior mean and variance of μ are given, respectively, by

$$\begin{aligned}E(\mu | \mathbf{x}, \sigma^2) &\equiv \mu^* = \hat{\mu} \frac{\frac{n}{\sigma^2}}{\frac{n}{\sigma^2} + \frac{T}{\sigma^2}} + \eta \frac{\frac{T}{\sigma^2}}{\frac{n}{\sigma^2} + \frac{T}{\sigma^2}} \\ &= \hat{\mu} \frac{n}{n + T} + \eta \frac{T}{n + T}\end{aligned}\quad (10)$$

where $\hat{\mu}$ is the sample mean as given in (8) and

$$\text{var}(\mu | \mathbf{x}, \sigma^2) = \frac{\sigma^2}{T + n} \quad (11)$$

In practical applications, usually the emphasis is placed on obtaining the posterior distribution of μ , not least because it is more difficult to formulate prior beliefs about the variance, σ^2 (let alone the whole covariance matrix in the multivariate setting). Often, then, the variance (covariance matrix) is estimated outside of the regression model and then fed into it, as if it were the “known” variance (covariance matrix).¹³ Nevertheless, for completeness, we provide σ^2 's posterior distribution—an inverted χ^2 ,

$$p(\sigma^2 | \mathbf{x}) = \text{Inv} - \chi^2(v^*, c^{2*}) \quad (12)$$

where

$$v^* = v_0 + n, \quad (13)$$

$$c^{2*} = \frac{1}{v^*} \left(v_0 c_0^2 + (n-1)s^2 + \frac{Tn}{T+n} (\hat{\mu} - \eta)^2 \right) \quad (14)$$

and s^2 is the unbiased sample estimator of the normal variance as given in (8). Using (13) and (14), one can now compute the posterior mean and variance of σ^2 as, respectively¹⁴

$$E(\sigma^2 | x) = \frac{v^*}{v^* - 2} c^{2*} \quad (15)$$

and

$$\text{var}(\sigma^2 | x) = \frac{2v^{*2}}{(v^* - 2)^2(v^* - 4)} (c^{2*})^2 \quad (16)$$

When the posterior is not of known form and is computed numerically (through simulations), so are the posterior point estimates, as well as the distributions of any functions of these estimates (see Chapter 4 in Rachev et al., 2008).

Bayesian Intervals

The point estimate for the center of the posterior distribution is not too informative if the posterior uncertainty is significant. To assess the degree of uncertainty, a posterior $(1 - \alpha)100\%$ interval $[a, b]$, called a *credible interval*, can be constructed. The probability that the unknown parameter, θ , falls between a and b is $(1 - \alpha)100\%$,

$$P(a < \theta < b | x) = \int_a^b p(\theta | x) d\theta = 1 - \alpha$$

For reasons of convenience, the interval bounds may be determined so that an equal probability, $\alpha/2$, is left in the tails of the posterior distribution. For example, a could be chosen to be the 0.25th quantile, while b —the 0.75th quantile. The interpretation of the credible interval is often mistakenly ascribed to the classical confidence interval. In the classical setting, $(1 - \alpha)100\%$ is a coverage probability—if ar-

bitrarily many repeated samples of data are recorded, $(1 - \alpha)100\%$ of the corresponding confidence intervals will contain θ —a much less intuitive interpretation.

The credible interval is computed either analytically, by finding the theoretical quantiles of the posterior distribution (when it is of known form), or numerically, by finding the empirical quantiles using the simulations of the posterior density (see Chapter 4 in Rachev et al., 2008).¹⁵

Bayesian Hypothesis Comparison

The title of this section¹⁶ abuses the usual terminology by intentionally using “comparison” instead of “testing” in order to stress that the Bayesian framework affords one more than the mere binary reject/do-not-reject decision of the classical hypothesis testing framework. In the classical setting, the probability of a hypothesis (null or alternative) is either 0 or 1 (since frequentist statistics considers parameters as fixed, although unknown, quantities).

In contrast, in the Bayesian setting (where parameters are treated as random variables), the probability of a hypothesis can be computed (and is different from 0 or 1, in general), allowing for a true hypothesis comparison.¹⁷

Suppose one wants to compare the null hypothesis

$$H_0 : \theta \text{ is in } \Theta_0$$

with the alternative hypothesis

$$H_1 : \theta \text{ is in } \Theta_1$$

where Θ_0 and Θ_1 are disjoint sets of possible values for the unknown parameter θ . As with point estimates and credible intervals, hypothesis comparison is entirely based on θ 's posterior distribution. We compute the posterior probabilities of the null and alternative hypotheses,

$$P(\theta \text{ is in } \Theta_0 | x) = \int_{\Theta_0} p(\theta | x) d\theta \quad (17)$$

and

$$P(\theta \text{ is in } \Theta_1 | x) = \int_{\Theta_1} p(\theta | x) d\theta \quad (18)$$

respectively. These posterior hypotheses probabilities naturally reflect both the prior beliefs and the data evidence about θ . An informed decision can now be made incorporating that knowledge. For example, the posterior probabilities could be employed in scenario-generation—a tool of great importance in risk analysis.

The Posterior Odds Ratio

Although the framework outlined in the previous section is generally sufficient to make an informed decision about the relevance of hypotheses, we briefly discuss a somewhat more formal approach for Bayesian hypothesis testing. That approach consists of summarizing the posterior relevance of the two hypotheses into a single number—the posterior odds ratio. The posterior odds ratio is the ratio of the weighted likelihoods for the model parameters under the null hypothesis and under the alternative hypothesis, multiplied by the prior odds. The weights are the prior parameter distributions (thus, parameter uncertainty is taken into account).¹⁸

Denote the a priori probability of the null hypothesis by α . Then, the prior odds are the ratio $\alpha/(1 - \alpha)$. The posterior odds, denoted by PO, are simply the prior odds updated with the information contained in the data and are given by

$$\text{PO} = \frac{\alpha}{1 - \alpha} \times \frac{\int L(\theta | x, H_0) \pi(\theta) d\theta}{\int L(\theta | x, H_1) \pi(\theta) d\theta} \quad (19)$$

where $L(\theta | x, H_0)$ is the likelihood function reflecting the restrictions imposed by the null hypothesis and $L(\theta | x, H_1)$ is the likelihood function under the alternative hypothesis.

When no prior evidence in favor or against the null hypothesis exists, the prior odds is usually set equal to one. A low value of the posterior odds generally indicates evidence against the null hypothesis.

BAYESIAN PREDICTIVE INFERENCE

After performing Bayesian posterior inference about the parameters of the data-generating process, one may use the process to predict the realizations of the random variable ahead in time. The purpose of such a prediction could be to test the predictive power of the model (for example, by analyzing a metric for the distance between the model's predictions and the actual realizations) as part of a backtesting procedure or to directly use it in the decision-making process.

As in the case of posterior inference, predictive inference provides more than simply a point prediction—one has available the whole predictive distribution (either analytically or numerically) and thus increased modeling flexibility.¹⁹ The density of the predictive distribution is the sampling (data) distribution weighted by the posterior parameter density. By averaging out the parameter uncertainty (contained in the posterior), the predictive distribution provides a superior description of the model's predictive ability. In contrast, the classical approach to prediction involves computing point predictions or prediction intervals by plugging in the parameter estimates into the sampling density, treating those estimates as if they were the true parameter values.

Denoting the sampling and the posterior density by $f(x | \theta)$ and $p(\theta | x)$, respectively, the predictive density one step ahead is given by²⁰

$$f(x_{+1} | x) = \int f(x_{+1} | \theta) p(\theta | x) d\theta \quad (20)$$

where x_{+1} denotes the one-step-ahead realization. Notice that since we integrate (average) over the values of θ , the predictive distribution is independent of θ and depends only on the past realizations of the random variable X —it describes the process we assume has generated the data. The predictive density could be used to obtain a point prediction (for example, the predictive mean) or an interval prediction (similar in spirit to the Bayesian interval

discussed above) or to perform a hypotheses comparison.

ILLUSTRATION: POSTERIOR TRADE-OFF AND THE NORMAL MEAN PARAMETER

Using an illustration, we show the effects prior distributions have on posterior inference. For simplicity, we look at the case of a normal data distribution with a known variance, $\sigma^2 = 1$. That is, we need to elicit a prior distribution of the mean parameter, μ , only. We investigate the following prior assumptions:

1. A noninformative, improper prior (Jeffreys' prior): $\pi(\mu) \propto 1$.
2. A noninformative, proper prior: $\pi(\mu) = N(\eta, \tau^2)$, where $\eta = 0$ and $\tau = 10^6$.
3. An informative conjugate prior with subjectively determined hyperparameters: $\pi(\mu) = N(\eta, \tau^2)$, where $\eta = 0.02$ and $\tau = 0.1$.

As mentioned earlier in the entry, the relative strengths of the prior and the sampling distribution determine the degree of trade-off of prior and data information in the posterior. When the amount of available data is large, the sampling distribution dominates the prior in the posterior inference. (In the limit, as the number of observations grows indefinitely, only the sampling distribution plays a role in determining posterior results.²¹) To illustrate this sample-size effect, we consider the following two samples of data:

1. The monthly return on the S&P 500 stock index for the period January 1999 through December 2005 (a total of 192 returns).
2. The monthly return on the S&P 500 stock index for the period January 2005 through December 2005 (a total of 12 returns).

Let us denote the return data by the $n \times 1$ vector $\mathbf{r} = (r_1, r_2, \dots, r_n)$, where $n = 192$ or

$n = 12$. We assume that the sampling (data) distribution is normal, $R \sim N(\mu, \sigma^2)$. Combining the normal likelihood and the noninformative improper prior, we obtain for the posterior distribution of μ

$$\begin{aligned} p(\mu | \mathbf{r}, \sigma^2 = 1) &\propto (2\pi)^{-n/2} \exp\left(-\frac{\sum_{i=1}^n (r_i - \mu)^2}{2}\right) \\ &\propto \exp\left(-\frac{n(\mu - \hat{\mu})^2}{2}\right) \end{aligned} \quad (21)$$

where $\hat{\mu}$ is the sample mean as given in (8). Therefore, the posterior of μ is a normal distribution with mean $\hat{\mu}$ and variance $1/n$. As expected, the data completely determine the posterior distributions for both data samples, since we assumed prior ignorance about μ .

When a normal prior for μ , $N(\eta, \tau^2)$, is asserted, the posterior can be shown to be normal as well. In the generic case, for an arbitrary data variance σ^2 , we have

$$\begin{aligned} p(\mu | \mathbf{r}, \sigma^2) &= (2\pi\sigma^2)^{-n/2} \exp\left(-\frac{\sum_{i=1}^n (r_i - \mu)^2}{\sigma^2}\right) \\ &\quad \times (2\pi\tau^2)^{-1/2} \exp\left(-\frac{(\mu - \eta)^2}{2\tau^2}\right) \\ &\propto \exp\left(-\frac{(\mu - \mu^*)^2}{2\tau^{2*}}\right) \end{aligned} \quad (22)$$

where the posterior mean, μ^* , is

$$\mu^* = \hat{\mu} \frac{\frac{n}{\sigma^2}}{\frac{n}{\sigma^2} + \frac{1}{\tau^2}} + \eta \frac{\frac{1}{\tau^2}}{\frac{n}{\sigma^2} + \frac{1}{\tau^2}} \quad (23)$$

and the posterior variance, τ^{2*} , is

$$\tau^{2*} = \frac{1}{\frac{n}{\sigma^2} + \frac{1}{\tau^2}} \quad (24)$$

Notice that the posterior mean is a weighted average of the sample mean, $\hat{\mu}$, and the prior mean, η . The quantities $1/\sigma^2$ and $1/\tau^2$ have self-explanatory names: *data precision* and *prior precision*, respectively. The higher the precision, the more concentrated the distribution around its mean value.²² Let us see how the information trade-off between the data and the prior is reflected in the values of the posterior parameters.

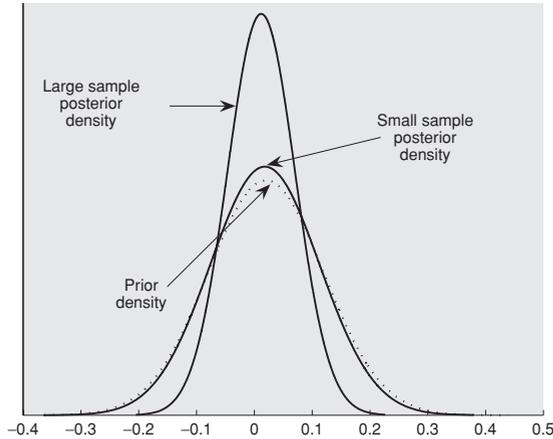

Figure 1 Sample Size and Posterior Trade-Off for the Normal Mean Parameter: The Case of Informative Prior

In the case of the noninformative, proper prior, $\tau = 10^6$. The rightmost term in (23) is then negligibly small and the posterior mean is very close to the sample mean: $\mu^* \approx \hat{\mu}$, while the posterior variance in (24) is approximately equal to $1/n$ (substituting in $\sigma^2 = 1$). That is, for both data samples, the noninformative proper prior produced posteriors almost the same as in the case of the noninformative improper prior, as expected.

Consider how the posterior is affected when informativeness of the prior is increased, as in the third prior scenario. Figure 1 helps visualize the posterior trade-off for the long and short data samples, respectively. The smaller the amount of observed data, the larger the influence of the prior on the posterior (the “closer” the posterior to the prior).

KEY POINTS

- The degree of posterior information trade-off has two determinants: strength of the prior information and amount of historical data available.
- Informative prior beliefs can modify substantially the information content of the observed data.

- Informative prior elicitation most commonly involves two steps: selecting the form of the prior distribution (usually, an analytically convenient one) and specifying its parameters (the hyperparameters) to reflect the prior beliefs.
- Noninformative priors help account for estimation uncertainty without substantially influencing the posterior parameter inference.
- A conjugate prior distribution guarantees that the resulting posterior distribution is of the same form as the prior.
- The posterior distribution can be summarized with point estimates, such as posterior mean, posterior median, posterior standard deviation, and posterior quantiles, as well as interval estimates.
- As in the case of posterior inference, when forecasting, one has available the whole predictive distribution of the random variable(s).

NOTES

1. See Chapter 3 in Berger (1985), Chapter 3 in Leonard and Hsu (1999), Berger (1990, 2006), and Garthwaite, Kadane, and O’Hagan (2005), among others.
2. The median is a measure of the center of a distribution alternative to the mean, defined as the value of the random variable, which divides the probability mass in halves. The median is the typical value the random variable takes. It is a more robust measure than the mean as it is not affected by the presence of extreme observations and, unless the distribution is symmetric, is not equal to the mean.
3. A random variable, $X \sim N(\mu, \sigma^2)$, is transformed into a standard normal random variable, $Z \sim N(0, 1)$, by subtracting the mean and dividing by its standard deviation:

$$Z = \frac{X - \mu}{\sigma}$$

4. Reference priors are another class of noninformative priors developed by Berger and

Bernardo (1992); see also Bernardo and Smith (1994). Their derivation is somewhat involved and applications in the field of finance are rare. One exception is Aguilar and West (2000).

5. Suppose a density has the form $f(x - \mu)$. The parameter μ is called the *location parameter* if it only appears within the expression $(x - \mu)$. The density, f , is then called a location density. For example, the normal density, $N(\mu, \sigma^{2*})$, is a location density when σ^{2*} is fixed.
6. Suppose a density has the form $\frac{1}{\sigma} f(\frac{x}{\sigma})$. The parameter σ is the *scale parameter*. For example, the normal density, $N(\mu^*, \sigma^2)$, is a scale density when the mean is fixed at some μ^* .
7. See Jeffreys (1961). In general, Jeffreys' prior of a parameter (vector), θ , is given by

$$\pi(\theta) = |I(\theta)|^{1/2}$$

where $I(\theta)$ is the so-called Fisher's information matrix for θ , given by

$$I(\theta) = -E \left(\frac{\partial^2 \log f(x|\theta)}{\partial \theta \partial \theta'} \right)$$

and the expectation is with respect to the random variable X , whose density function is $f(x|\theta)$. Notice that applying the expression for $\pi(\theta)$ to, for example, the normal distribution, one obtains the joint prior $\pi(\mu, \sigma) \propto 1/\sigma^2$, instead of the one in (5). Nevertheless, Jeffreys advocated the use of (5) since he assumed independence of the location and scale parameters.

8. The Student's t -distribution has heavier tails than the normal distribution. For values of ν less than 2, its variance is not defined.
9. Technically speaking, for the parameters of all distributions belonging to the exponential family there are conjugate prior distributions.
10. Notice that μ and σ^2 are not independent in (6). This prior scenario is the so-called natu-

ral conjugate prior scenario. Natural conjugate priors are priors whose functional form is the same as the likelihood's. The joint prior density of μ and σ^2 , $\pi(\mu, \sigma^2)$ can be represented as the product of a conditional and a marginal density: $\pi(\mu, \sigma^2) = \pi(\mu|\sigma^2)\pi(\sigma^2)$. If the dependence of the normal mean and variance is deemed inappropriate for the particular application, it is possible to make them independent and still benefit from the convenience of their functional forms—by eliciting a prior for μ as in (2).

11. An unbiased estimator of a parameter θ is a function of the data (a statistic), whose expected value is θ . The statistics $\hat{\mu}$ and s^2 are the so-called sufficient statistics for the normal distribution—knowing them is sufficient to uniquely determine the normal distribution that generated the data. In empirical Bayesian analysis, the hyperparameters are usually functions of the sufficient statistics of the sampling distribution.
12. In decision theory, loss functions are used to assess the impact of an action. In the context of parameter inference, if θ^* is the true parameter value, the loss associated with employing the estimate $\hat{\theta}$ instead of θ^* is represented by the loss function $L(\theta^*, \hat{\theta})$. One approach to estimating θ is to determine the value that minimizes the expected resulting loss. In Bayesian analysis, we minimize the expected posterior loss: its expectation is computed with respect to θ 's posterior distribution. It can be shown that the estimate of central tendency that minimizes the expected, posterior, squared-error loss function, $L(\theta^*, \hat{\theta}) = (\theta^* - \hat{\theta})^2$, is the posterior mean, while the estimate that minimizes the expected, posterior, absolute-error loss function, $L(\theta^*, \hat{\theta}) = |\theta^* - \hat{\theta}|$, is the posterior median.
13. One example for such an approach is the Black-Litterman model. See Black and Litterman (1991).

14. These are the expressions for expected value and variance of a random variable with the inverted χ^2 distribution.
15. A special type of Bayesian interval is the highest posterior density (HPD) interval. It is built so as to include the values of θ that have the highest posterior probability (the most likely values). When the posterior is symmetric and has a single peak (is unimodal), credible and HPD intervals coincide. With very skewed posterior distributions, however, the two intervals look very different. A disadvantage of HPD intervals is that they could be disjoint when the posterior has more than one peak (is multimodal). In unimodal settings, the Bayesian HPD interval obtained under the assumptions of a noninformative prior corresponds to the classical confidence interval.
16. In this section, we emphasize a practical approach to Bayesian hypothesis testing. For a rigorous description of Bayesian hypothesis testing, see, for example, Zellner (1971).
17. In the classical setting, the decision to reject or not the null hypothesis is made on the basis of the realization of a test statistic—a function of the data—whose distribution is known. The p -value of the hypothesis test is the probability of obtaining a value of the statistic as extreme or more extreme than the one observed. The p -value is compared to the test's significance level, which represents the predetermined probability of rejecting the null hypothesis falsely. If the p -value is sufficiently small (smaller than the significance level), the null hypothesis is rejected. The p -value is often mistakenly given the interpretation of a posterior probability of the null hypothesis. It has been suggested that a low p -value, interpreted by many as strong evidence against the null hypothesis, could be in fact quite a misleading signal about evidence strength. See, for example, Berger (1985) and Stambaugh (1999).
18. The posterior odds ratio bears similarity to the likelihood ratio which is at the center of most frequentist hypothesis tests. As its name suggests, the likelihood ratio is the ratio of the (maximized) likelihoods under the null and the alternative hypotheses.
19. The predictive density is usually of known (closed) form under conjugate prior assumptions.
20. Here, we assume that θ is continuous, which is the case in most financial applications.
21. This statement is valid only if one assumes that the data-generating process remains unchanged through time.
22. The posterior mean is an example for the shrinkage effect that combining prior and data information has.

Abstract: Linear regression is the “workhorse” of financial modeling. Cornerstone applications, such as asset pricing models, as well as time series models, are built around linear regression’s methods and tools. Casting the linear regression methodology in a Bayesian setting helps account for estimation uncertainty, allows for integration of prior information, and makes accessible the Bayesian numerical simulation framework.

In this entry, we lay the foundations of *Bayesian linear regression* estimation. We start with a univariate model with Gaussian innovations and consider two cases for prior distributional assumptions—diffuse and informative. Then, we show how one could incorporate knowledge that the sample is not homogeneous with respect to the variance, for example, due to a structural break. Finally, multivariate regression estimation is discussed.

THE UNIVARIATE LINEAR REGRESSION MODEL

The univariate linear regression model attempts to explain the variability in one variable (called the dependent variable) with the help of one or more other variables (called explanatory or independent variables) by asserting a linear relationship between them. We write the model as

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_{K-1} X_{K-1} + \epsilon \quad (1)$$

where

- Y = dependent variable;
- X_k = independent (explanatory) variables,
 $k = 1, \dots, K - 1$;
- α = regression intercept;
- β_k = regression (slope) coefficients, $k =$
 $1, \dots, K - 1$, representing the effect a
unit change in X_k , $k = 1, \dots, K - 1$, has
on Y , keeping the remaining independ-
ent variables, X_j , $j \neq k$, fixed;
- ϵ = regression disturbance.

The regression disturbance is the source of randomness about the linear (deterministic) relationship between the dependent and independent variables. Whereas $\alpha + \beta_1 X_1 + \dots + \beta_{K-1} X_{K-1}$ represents the part of Y 's variability explained by X_k , $k = 1, \dots, K - 1$, ϵ represents the portion of Y 's variability left unexplained. It is usually assumed that the independent variables are fixed (nonstochastic).

Suppose that we have n observations of the dependent and the independent variables available. These data are then described by

$$\begin{aligned} y_i &= \alpha + \beta_1 x_{1,i} + \dots + \beta_{K-1} x_{K-1,i} + \epsilon_i \\ i &= 1, \dots, n \end{aligned} \quad (2)$$

The subscript i , $i = 1, \dots, n$, refers to the i th observation of the respective random variable. To describe the source of randomness, ϵ , one needs to make a distributional assumption about it. For simplicity, assume that ϵ_i , $i = 1, \dots, n$, are independently and identically distributed (IID) with the normal distribution and have zero means and (equal) variances, σ^2 . Then, the dependent variable, Y , has a normal distribution as well,

$$y_i \sim N(\mu_i, \sigma^2) \quad (3)$$

where $\mu_i = \alpha + \beta_1 x_{1,i} + \dots + \beta_{K-1} x_{K-1,i}$. Notice that the constant-variance assumption in (3) is quite restrictive. We come back to this issue later in the entry.

The expression in (2) is often written in the following compact form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon} \quad (4)$$

where \mathbf{y} is a $n \times 1$ vector,

$$\mathbf{y} = \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix}$$

$\boldsymbol{\beta}$ is a $(K) \times 1$ vector,

$$\boldsymbol{\beta} = \begin{pmatrix} \alpha \\ \beta_1 \\ \vdots \\ \beta_{K-1} \end{pmatrix}$$

\mathbf{X} is an $n \times (K)$ matrix whose first column consists of ones,

$$\mathbf{X} = \begin{pmatrix} 1 & x_{1,1} & \cdots & x_{K-1,1} \\ 1 & x_{1,2} & \cdots & x_{K-1,2} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{1,n} & \cdots & x_{K-1,n} \end{pmatrix}$$

and $\boldsymbol{\epsilon}$ is an $n \times 1$ vector,

$$\boldsymbol{\epsilon} = \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_n \end{pmatrix}$$

We write the normal distributional assumption for the regression disturbances in compact form as

$$\boldsymbol{\epsilon} \sim N(\mathbf{0}, \sigma^2 I_n)$$

where I_n is an $(n \times n)$ identity matrix. The parameters in (4) we need to estimate are $\boldsymbol{\beta}$ and σ^2 . Assuming normally distributed disturbances, we write the likelihood function for the model parameters as

$$\begin{aligned} L(\alpha, \beta_1, \dots, \beta_{K-1}, \sigma \mid \mathbf{y}, \mathbf{X}) \\ = (2\pi\sigma^2)^{-n/2} \exp \left\{ -\frac{1}{2\sigma^2} \sum_{i=1}^n (y_i - \alpha \right. \\ \left. - \beta_1 x_{1,i} - \dots - \beta_{K-1} x_{K-1,i})^2 \right\} \end{aligned}$$

Or, in matrix notation, we have the likelihood function for the parameters of a multivariate normal distribution,

$$L(\beta, \sigma | \mathbf{y}, \mathbf{X}) = (2\pi\sigma^2)^{-n/2} \times \exp \left\{ -\frac{1}{2\sigma^2} (\mathbf{y} - \mathbf{X}\beta)' (\mathbf{y} - \mathbf{X}\beta) \right\} \quad (5)$$

Bayesian Estimation of the Univariate Regression Model

In the classical setting, the regression parameters are usually estimated by maximizing the model's likelihood with respect to β and σ^2 , for instance, the likelihood in (5) if the normal distribution is assumed. When disturbances are assumed to be normally distributed, the maximum likelihood and the ordinary least squares (OLS) methods produce identical parameter estimates. It can be shown that the OLS estimator of the regression coefficients vector, β , is given by

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \quad (6)$$

where the prime symbol ($'$) denotes a matrix transpose.¹ The estimator of σ^2 is²

$$\hat{\sigma}^2 = \frac{1}{n-K} (\mathbf{y} - \mathbf{X}\hat{\beta})' (\mathbf{y} - \mathbf{X}\hat{\beta}) \quad (7)$$

To account for the parameters' estimation risk and to incorporate prior information, regression estimation can be cast in a Bayesian setting. We consider two prior scenarios—a *diffuse improper prior* and an *informative conjugate prior* for the regression parameter vector, (β, σ^2) .

Diffuse Improper Prior

The joint diffuse improper prior for β and σ^2 is given by

$$\pi(\beta, \sigma^2) \propto \frac{1}{\sigma^2} \quad (8)$$

where the regression coefficients can take any real value, $-\infty < \beta_k < \infty$, for $k = 1, \dots, K$,

and the disturbance variance is positive, $\sigma^2 > 0$.

Combining the likelihood in (5) and the prior above, we obtain the posteriors of the model parameters as follows:

- The posterior distribution of β conditional on σ^2 is (multivariate) normal:

$$p(\beta | \mathbf{y}, \mathbf{X}, \sigma^2) = N(\hat{\beta}, (\mathbf{X}'\mathbf{X})^{-1}\sigma^2) \quad (9)$$

where $\hat{\beta}$ is the OLS estimate in (6) and $(\mathbf{X}'\mathbf{X})^{-1}\sigma^2$ is the covariance matrix of $\hat{\beta}$.

- The posterior distribution of σ^2 is inverted- χ^2 :

$$p(\sigma^2 | \mathbf{y}, \mathbf{X}) = \text{Inv-}\chi^2(n-K, \hat{\sigma}^2) \quad (10)$$

where $\hat{\sigma}^2$ is the estimator of σ^2 in (7).

It could be useful to obtain the marginal (unconditional) distribution of β in order to characterize it independently of σ^2 (as in practical applications, the variance is an unknown parameter).³ It can be shown, by integrating the joint posterior distribution

$$p(\beta, \sigma^2 | \mathbf{y}, \mathbf{X}) = p(\beta | \mathbf{y}, \mathbf{X}, \sigma^2) p(\sigma^2 | \mathbf{y}, \mathbf{X})$$

with respect to σ^2 , that β 's unconditional posterior distribution is a multivariate Student's t distribution with a kernel given by⁴

$$p(\beta | \mathbf{y}, \mathbf{X}) \propto \left((n-K) + (\beta - \hat{\beta})' \frac{\mathbf{X}'\mathbf{X}}{\hat{\sigma}^2} (\beta - \hat{\beta}) \right)^{-n/2} \quad (11)$$

Notice that integrating σ^2 out makes β 's distribution more heavy-tailed, duly reflecting the uncertainty about σ^2 's true value. Although β 's mean vector is unchanged, its variance increased (on average) by the term $\nu/(\nu-2)$:

$$\Sigma_{\beta} = \hat{\sigma}^2 (\mathbf{X}'\mathbf{X})^{-1} \frac{\nu}{\nu-2}$$

where $\nu = n - K$ is the degrees of freedom parameter of the multivariate Student's t distribution above.

In conclusion of our discussion of the posteriors in the diffuse improper prior scenario, suppose we are interested particularly in one

of the regression coefficients, say β_k . For example, β_k could be the return on a factor (size, value, momentum, etc.) in a multifactor model of stock returns. It can be shown that the standardized β_k has a Student's t distribution with $n - K$ degrees of freedom as its marginal posterior distribution,

$$\frac{\beta_k - \widehat{\beta}_k}{(h_{k,k})^{1/2}} \mid \mathbf{y}, \mathbf{X} \sim t_{n-K} \quad (12)$$

where $h_{k,k}$ is the k th diagonal element of $\widehat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1}$ and $\widehat{\beta}_k$ is the OLS estimate of β_k (the corresponding component of $\widehat{\beta}$). Bayesian intervals for β_k can then be constructed analytically.

Informative Prior

Under the normality assumption for the regression errors in (4), one can make use of the natural conjugate framework to reflect the existing prior knowledge and to obtain convenient analytical posterior results. Thus, let us assume that the regression coefficients vector, β , has a normal prior distribution (conditional on σ^2) and σ^2 —an inverted- χ^2 prior distribution:

$$\beta \mid \sigma \sim N(\beta_0, \sigma^2 \mathbf{A}) \quad (13)$$

and

$$\sigma^2 \sim \text{Inv-}\chi^2(v_0, c_0^2) \quad (14)$$

Four parameters have to be determined a priori: β_0 , \mathbf{A} , v_0 , and c_0^2 . The scale matrix \mathbf{A} is often chosen to be $\tau^{-1}(\mathbf{X}'\mathbf{X})^{-1}$ in order to obtain a prior covariance the same as the covariance matrix of the OLS estimator of β up to a scaling constant. Varying the (scale) parameter, τ , allows one to adjust the degree of confidence one has that β 's mean is β_0 —the smaller the value of τ , the greater the degree of uncertainty about β .

The easiest way to assert the prior mean, β_0 , is to fix it at some default value (such as $\mathbf{0}$, depending on the estimation context), unless more specific prior information is available, or to set it equal to the OLS estimate, $\widehat{\beta}$, obtained from

running the regression (4) on a prior sample of data.⁵

The parameters of the inverted- χ^2 distribution could be asserted using a prior sample of data as follows:

$$\begin{aligned} v_0 &= n_0 - K \\ c_0^2 &= \frac{1}{v_0} (\mathbf{y}_0 - \mathbf{X}_0 \widehat{\beta}_0)' (\mathbf{y}_0 - \mathbf{X}_0 \widehat{\beta}_0) \end{aligned}$$

where the subscript, 0, refers to the prior data sample. If no prior data sample is available, the inverted- χ^2 hyperparameters could be specified indirectly, by expressing beliefs about the prior mean and variance of σ^2 .⁶

The posterior distributions for the model parameters, β and σ^2 have the same form as the prior distributions, however, their parameters are updated to reflect the data information, along with the prior beliefs.

- The posterior for β is

$$p(\beta \mid \mathbf{y}, \mathbf{X}, \sigma^2) = N(\beta^*, \Sigma_\beta) \quad (15)$$

where the posterior mean and covariance matrix of β are given by

$$\beta^* = (\mathbf{A}^{-1} + \mathbf{X}'\mathbf{X})^{-1} (\mathbf{A}^{-1}\beta_0 + \mathbf{X}'\mathbf{X}\widehat{\beta}) \quad (16)$$

and

$$\Sigma_\beta = \sigma^2 (\mathbf{A}^{-1} + \mathbf{X}'\mathbf{X})^{-1} \quad (17)$$

We can observe that the posterior mean is a weighted average of the prior mean and the OLS estimator of β , as noted earlier in the entry as well.⁷

- The inverted- χ^2 posterior distribution of σ^2 is

$$p(\sigma^2 \mid \mathbf{y}, \mathbf{X}) = \text{Inv-}\chi^2(v^*, c^{2*}) \quad (18)$$

The parameters of σ^2 's posterior distribution are given by

$$v^* = v_0 + n \quad (19)$$

and

$$v^* c^{2*} = (n - K) \widehat{\sigma}^2 + (\beta_0 - \widehat{\beta})' \mathbf{H} (\beta_0 - \widehat{\beta}) + v_0 c_0^2 \quad (20)$$

where $\mathbf{H} = ((\mathbf{X}'\mathbf{X})^{-1} + \mathbf{A})^{-1}$

As earlier, we can derive the marginal posterior distribution of β by integrating σ^2 out of the joint posterior distribution. We obtain again a multivariate Student's t distribution, $t(v^*, \beta^*, Q)$,

$$p(\beta | \mathbf{y}, \mathbf{X}) \propto (v^* + (\beta - \beta^*)' \mathbf{Q}(\beta - \beta^*))^{-v^*/2} \quad (21)$$

where $\mathbf{Q} = (\mathbf{A}^{-1} + \mathbf{X}'\mathbf{X})/c^{2*}$

The mean of β remains the same, β^* (as it is independent of σ^2), while its unconditional (with respect to σ^2) covariance matrix is equal to $Q^{-1}v^*/(v^* - 2)$. The marginal posterior distribution for a single regression coefficient, β_k , can be shown to be

$$\frac{\beta_k - \beta_k^*}{(q_{k,k})^{1/2}} | \mathbf{y}, \mathbf{X} \sim t_{v_0+n-K} \quad (22)$$

where $q_{k,k}$ is the k th diagonal element of \mathbf{Q}^{-1} and β_k^* is the k th component of β^* .

Prediction

Suppose that we would like to predict the dependent variable, Y , p steps ahead in time and denote by the $p \times 1$ vector $\tilde{\mathbf{y}} = (y_{T+1}, y_{T+2}, \dots, y_{T+p})$ these future observations. We assume that the future observations of the independent variables are known and given by $\tilde{\mathbf{X}}$. The predictive density in the linear regression context can be expressed as,⁸

$$p(\tilde{\mathbf{y}} | \mathbf{y}, \tilde{\mathbf{X}}, \mathbf{X}) = \iint p(\tilde{\mathbf{y}} | \beta, \sigma^2, \tilde{\mathbf{X}}) \times p(\beta, \sigma^2 | \mathbf{y}, \mathbf{X}) d\beta, \sigma^2 \quad (23)$$

where $p(\beta, \sigma^2 | \mathbf{y}, \mathbf{X})$ is the joint posterior distribution of β and σ^2 .

It can be shown that the predictive distribution is multivariate Student's t . Under the diffuse improper prior scenario, the predictive distribution is

$$p(\tilde{\mathbf{y}} | \mathbf{y}, \tilde{\mathbf{X}}, \mathbf{X}) = t(n - K, \tilde{\mathbf{X}}\hat{\beta}, \mathbf{S}) \quad (24)$$

where $\mathbf{S} = \hat{\sigma}^2(I_p + \tilde{\mathbf{X}}(\mathbf{X}'\mathbf{X})^{-1}\tilde{\mathbf{X}}')$ and $\hat{\beta}$ is the posterior mean of β under the diffuse improper scenario. In the case of the informative prior,

the predictive distribution of $\tilde{\mathbf{y}}$ is

$$p(\tilde{\mathbf{y}} | \mathbf{y}, \tilde{\mathbf{X}}, \mathbf{X}) = t(v_0 + n, \tilde{\mathbf{X}}\beta^*, \mathbf{V}) \quad (25)$$

where $\mathbf{V} = c^{2*}(I_p + \tilde{\mathbf{X}}(\mathbf{A}^{-1} + \mathbf{X}'\mathbf{X})^{-1}\tilde{\mathbf{X}}')$ and β^* is the posterior mean of β in (16).

Certainly, it is again possible to derive the distribution for the predictive distribution for a single component of $\tilde{\mathbf{y}}$ —a univariate Student's t distribution—in the two scenarios, respectively,

$$\frac{\tilde{y}_k - \tilde{\mathbf{X}}^k\hat{\beta}_k}{s_{k,k}^{1/2}} \sim t_{n-K} \quad (26)$$

where $\tilde{\mathbf{X}}^k$ is the k th row of $\tilde{\mathbf{X}}$ (the observations of the independent variables pertaining to the k th future period), and $s_{k,k}$ is the k th diagonal element of the scale matrix, \mathbf{S} , in (24), and

$$\frac{\tilde{y}_k - \tilde{\mathbf{X}}^k\beta_k^*}{v_{k,k}^{1/2}} \sim t_{v_0+n-K} \quad (27)$$

where $v_{k,k}$ is the k th diagonal element of the scale matrix, \mathbf{V} , in (25).

The Case of Unequal Variances

We mentioned earlier in the entry that the equal-variance assumption in (3) might be somewhat restrictive. Two examples would help clarify what that means. First, suppose that the n observations of Y are collected through time. It is a common practice in statistical estimation to use the longest available data record, likely spanning many years. Changes in the underlying economic or financial paradigms, the way data are recorded, and so on, that might have occurred during the sample period might have caused the variance of the random variable (as well as its mean, for that matter) to shift.⁹ The equal-variance assumption would then lead to variance overestimation in the low-variance period(s) and variance underestimation in the high-variance period(s). When the variance (and/or mean) shifts permanently, the so-called “structural-break” models can be employed to reflect it.¹⁰

Second, if our estimation problem is based on observations recorded at a particular point in time (producing a cross-sectional sample), the equal-variance assumption might be violated again. All units in our sample could potentially have different variances, so that $\text{var}(y_i) = \sigma_i^2$, instead of $\text{var}(y_i) = \sigma^2$ as in (3), for $i = 1, \dots, n$. Estimation would then be severely hampered because this would imply a greater number of unknown parameters (variances and regression coefficients) than available data points.

In practice one would perhaps be able to identify groups of homogeneous sample units that can be assumed to have equal variances. Suppose, for instance, that the cross-sectional sample consists of small-cap and large-cap stock returns. One could then expect that the return variances (volatilities) across the two groups differ but assume that companies within each group have equal return volatilities. More generally, one could assume some form of functional relation among the unknown variances—this would serve to reduce the number of unknown parameters to estimate. We now provide one possible way to address the variance inequality in the case when the sample observations can be divided into two homogeneous (with respect to their variances) groups or when a structural break (whose timing we know) is present in the sample.¹¹

Denote the observations from the two groups by $\mathbf{y}_1 = (y_{1,1}, y_{1,2}, \dots, y_{1,n_1})$ and $\mathbf{y}_2 = (y_{2,1}, y_{2,2}, \dots, y_{2,n_2})$, so that $\mathbf{y} = (\mathbf{y}_1, \mathbf{y}_2)$ and $n_1 + n_2 = n$. The univariate regression setup in (1) is modified as

$$\begin{aligned} \mathbf{y}_1 &= \mathbf{X}_1\beta + \epsilon_1 \\ \mathbf{y}_2 &= \mathbf{X}_2\beta + \epsilon_2 \end{aligned} \quad (28)$$

where \mathbf{X}_1 and \mathbf{X}_2 are, respectively, $(n_1 \times K)$ and $(n_2 \times K)$ matrices of observations of the independent variables. The disturbances are assumed to be independent and distributed as

$$\begin{aligned} \epsilon_1 &\sim N(\mathbf{0}, \sigma_1^2 I_{n_1}) \\ \epsilon_2 &\sim N(\mathbf{0}, \sigma_2^2 I_{n_2}) \end{aligned} \quad (29)$$

where $\sigma_1^2 \neq \sigma_2^2$. The likelihood function for the model parameters, β , σ_1^2 , and σ_2^2 is given by

$$\begin{aligned} L(\beta, \sigma_1^2, \sigma_2^2 | \mathbf{y}, \mathbf{X}_1, \mathbf{X}_2) &\propto (\sigma_1^2)^{-\frac{n_1}{2}} (\sigma_2^2)^{-\frac{n_2}{2}} \\ &\times \exp\left(-\frac{1}{2\sigma_1^2}(\mathbf{y}_1 - \mathbf{X}_1\beta)'(\mathbf{y}_1 - \mathbf{X}_1\beta) \right. \\ &\quad \left. - \frac{1}{2\sigma_2^2}(\mathbf{y}_2 - \mathbf{X}_2\beta)'(\mathbf{y}_2 - \mathbf{X}_2\beta)\right) \end{aligned} \quad (30)$$

A noninformative diffuse prior can be asserted, as in (3.5), by assuming that the parameters are independent. The prior is written, then, as

$$\pi(\beta, \sigma_1, \sigma_2) \propto \frac{1}{\sigma_1\sigma_2}$$

It is straightforward to write out the joint posterior density of β , σ_1^2 , and σ_2^2 , which can be integrated with respect to the two variances to obtain the marginal posterior distribution of the regression coefficients vector. Zellner (1971) shows that the marginal posterior of β is the product of two multivariate Student's t densities.

$$p(\beta | \mathbf{y}, \mathbf{X}_1, \mathbf{X}_2) \propto t(v_1, \widehat{\beta}_1, S_1) \times t(v_2, \widehat{\beta}_2, S_2)$$

where, for $i = 1, 2$, $\widehat{\beta}_i$ is the OLS estimator of β in the two expressions in (28) viewed as separate regressions,

$$v_i = n_i - K, \quad S_i = \widehat{s}_i^2(\mathbf{X}_i' \mathbf{X}_i)$$

and

$$\widehat{s}_i^2 = \frac{1}{n_i - K} (\mathbf{y}_i - \mathbf{X}_i \widehat{\beta}_i)' (\mathbf{y}_i - \mathbf{X}_i \widehat{\beta}_i).$$

Zellner shows that the marginal posterior of β above can be approximated with a normal distribution (through a series of asymptotic expansions).

Illustration: The Univariate Linear Regression Model

We now provide an example to illustrate the posterior and predictive inference in a univariate linear regression model. We restrict our attention to the diffuse noninformative prior

and the informative prior discussed above, in order to take advantage of their analytical convenience.¹²

Our data consist of the monthly returns on 25 portfolios; the companies in each portfolio are ranked according to market capitalization and book-to-market (BM) ratios. The returns we use for model estimation span the period from January 1995 to December 2005 (a total of 132 time periods). We extract the factors that best explain the variability of returns of the 25 portfolios using principal components analysis. The first five factors explain around 95% of the variability and we use their returns as the independent variables in our linear regression model, making up the matrix X (the first column is a column of ones). The return on the portfolio consisting of the companies with the smallest size and BM ratios is the dependent variable, y . In addition, returns recorded for the months from January 1990 to December 1994 (a total

of 60 time periods) are employed to compute the hyperparameters of the informative prior distributions, in the manner explained in the previous section. Our interest centers primarily on the posterior inference for the regression coefficients, $\beta_k, k = 1, \dots, 6$ —the intercept and the five factor exposures (in the terminology of multifactor models).

Posterior Distributions

The prior and posterior parameter values for β are given in Table 1. Part A of the table presents the results under the diffuse improper prior assumption and Part B under the informative prior assumption. In parentheses are the posterior standard deviations of the regression coefficients.¹³ The OLS estimates of the regression coefficients are given by the posterior means in the diffuse prior scenario. Notice how the posterior mean of β under the informative prior is shrunk

Table 1 Posterior Inference for β

Notes: Part A contains posterior results under the diffuse improper prior; Part B contains posterior results under the informative prior.

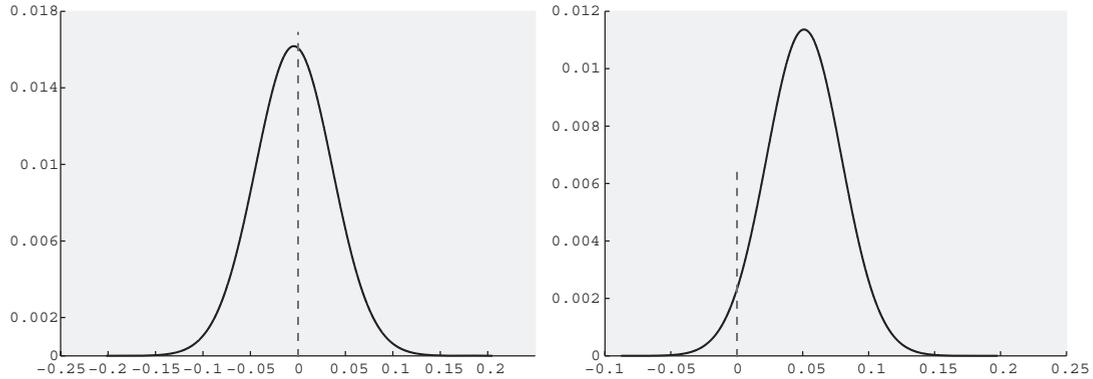

Figure 1 Posterior Densities of β_6 under the Two Prior Scenarios

Notes: The plot on the left refers to the diffuse improper prior; the plot on the right—to the informative prior.

away from the the OLS estimate and towards the prior value, for the chosen value of $\tau = 1$. We could introduce more uncertainty into the prior distribution of β (make it less informative) by choosing a smaller value of τ —the posterior mean of β would then be closer to the OLS estimate. Conversely, the stronger our prior belief about the mean of β , the closer the posterior mean would be to the prior mean.

Credible Intervals

Since the marginal posterior distribution of β_k , $k = 1, \dots, 6$, is of known form (Student's t), we can compute analytically the Bayesian confidence intervals for the regression coefficients. We provide the values of several quantiles of the posterior distribution of each β_k . For example, under the diffuse improper prior, the 95% (symmetric) Bayesian interval for β_2 is $(-0.3187, -0.3029)$, while, under the informative prior, the 99% (symmetric) Bayesian interval for β_6 is $(-0.0162, 0.1180)$.¹⁴

Hypothesis Comparison

In the frequentist regression tradition, testing the significance of the regression coefficients is of great interest—the validity of the null hypothesis $\beta_k = 0$ is examined. In the Bayesian

setting, we could evaluate and compare the posterior probabilities, $P(\beta_k > 0 | \mathbf{y}, \mathbf{X})$ and $P(\beta_k < 0 | \mathbf{y}, \mathbf{X})$ (given in Table 1 for each factor exposure). We could safely conclude that the exposures on Factor 1 through Factor 4 are different from zero—the mass of their posterior distributions is concentrated on either positive or negative values. For the exposure on Factor 5, the picture is less than clear-cut. Under the diffuse, improper prior, a bit over 50% of the posterior mass is below zero and the rest—above zero. Therefore, one would perhaps take the pertinence of this factor for explaining the variability of the return on the small-cap/small-BM portfolio with a grain of salt. Notice, however, how the situation changes in the informative-prior case. More than 95% of the posterior mass is above zero. The strong prior beliefs about a positive mean of β_6 lead to the conclusion that the exposure of the portfolio returns to Factor 5 is not zero. Figure 1 further illustrates these observations.

THE MULTIVARIATE LINEAR REGRESSION MODEL

Quite often in finance, and especially in investment management, one is faced with modeling data consisting of many assets whose returns

or other attributes are not independent. Casting the problem in a multivariate framework is one way to tackle dependencies between assets.¹⁵ In this section, we outline the basics of multivariate regression estimation within the Bayesian setting.¹⁶

Suppose that T observations are available on N dependent variables. We arrange these in the $T \times N$ matrix, \mathbf{y} ,

$$\mathbf{y} = \begin{pmatrix} \mathbf{y}_1 \\ \vdots \\ \mathbf{y}_t \\ \vdots \\ \mathbf{y}_T \end{pmatrix} = \begin{pmatrix} y_{1,1} & y_{1,2} & \cdots & y_{1,N} \\ \cdots & \cdots & \cdots & \cdots \\ y_{t,1} & y_{t,2} & \cdots & y_{t,N} \\ \cdots & \cdots & \cdots & \cdots \\ y_{T,1} & y_{T,2} & \cdots & y_{T,N} \end{pmatrix}$$

The multivariate linear regression is written as

$$\mathbf{y} = \mathbf{X}\mathbf{B} + \mathbf{U} \quad (31)$$

where

$\mathbf{X} = T \times K$ matrix of observations of the K independent variables,

$$\mathbf{X} = \begin{pmatrix} \mathbf{x}_1 \\ \vdots \\ \mathbf{x}_t \\ \vdots \\ \mathbf{x}_T \end{pmatrix} = \begin{pmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,K} \\ \cdots & \cdots & \cdots & \cdots \\ x_{t,1} & x_{t,2} & \cdots & x_{t,K} \\ \cdots & \cdots & \cdots & \cdots \\ x_{T,1} & x_{T,2} & \cdots & x_{T,K} \end{pmatrix}$$

$\mathbf{B} = K \times N$ matrix of regression coefficients,

$$\mathbf{B} = \begin{pmatrix} \alpha \\ \beta_1 \\ \cdots \\ \beta_K \end{pmatrix} = \begin{pmatrix} \alpha_1 & \alpha_2 & \cdots & \alpha_N \\ \beta_{1,1} & \beta_{1,2} & \cdots & \beta_{1,N} \\ \cdots & \cdots & \cdots & \cdots \\ \beta_{K,1} & \beta_{K,2} & \cdots & \beta_{K,N} \end{pmatrix}$$

$\mathbf{U} = T \times N$ matrix of regression disturbances,

$$\mathbf{U} = \begin{pmatrix} \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_t \\ \vdots \\ \mathbf{u}_T \end{pmatrix} = \begin{pmatrix} u_{1,1} & u_{1,2} & \cdots & u_{1,N} \\ \cdots & \cdots & \cdots & \cdots \\ u_{t,1} & u_{t,2} & \cdots & u_{t,N} \\ \cdots & \cdots & \cdots & \cdots \\ u_{T,1} & u_{T,2} & \cdots & u_{T,N} \end{pmatrix}$$

The first column of \mathbf{X} usually consists of ones to reflect the presence of an intercept. In the multivariate setting, the usual linear regression assumption that the disturbances are IID

means that each row of \mathbf{U} is an independent realization from the same N -dimensional multivariate distribution. We assume that this distribution is multivariate normal with zero mean and covariance matrix, Σ ,

$$\mathbf{u}_t \sim N(\mathbf{0}, \Sigma) \quad (32)$$

for $t = 1, \dots, T$. The off-diagonal elements of Σ are nonzero, as we assume the dependent variables are correlated, and the covariance matrix contains N variances and $N(N-1)/2$ distinct covariances.

Using the expression for the density of the multivariate normal distribution, we write the likelihood function for the unknown model parameters, \mathbf{B} and Σ , as¹⁷

$$L(\mathbf{B}, \Sigma | \mathbf{Y}, \mathbf{X}) \propto |\Sigma|^{-T/2} \times \exp\left(-\frac{1}{2} \sum_{t=1}^T (\mathbf{y}_t - \mathbf{x}_t \mathbf{B}) \Sigma^{-1} (\mathbf{y}_t - \mathbf{x}_t \mathbf{B})'\right) \quad (33)$$

where $|\Sigma|$ is the determinant of the covariance matrix. We now turn to specifying the prior distributional assumptions for \mathbf{B} and Σ .

Diffuse Improper Prior

The lack of specific prior knowledge about the elements of \mathbf{B} and Σ can be reflected by employing the Jeffreys' prior, which, in the multivariate setting, takes the form¹⁸

$$\pi(\mathbf{B}, \Sigma) \propto |\Sigma|^{-\frac{N+1}{2}} \quad (34)$$

The posterior distributions parallel those in the univariate case. With the risk of stating the obvious, note that \mathbf{B} is a random matrix; therefore, its posterior distribution, conditional on Σ , will be a generalization of the multivariate normal posterior distribution in (9). To describe it, we first vectorize (expand column-wise) the matrix of regression coefficients, \mathbf{B} , and denote the

resulting $KN \times 1$ vector by β ,

$$\beta = \text{vec}(\mathbf{B}) = \begin{pmatrix} \alpha' \\ \beta'_1 \\ \vdots \\ \beta'_K \end{pmatrix}$$

by stacking vertically the columns of \mathbf{B}' . It can be shown that β 's posterior distribution, conditional on Σ , is a multivariate normal given by

$$p(\beta | \mathbf{Y}, \mathbf{X}, \Sigma) = N(\hat{\beta}, \Sigma \otimes (\mathbf{X}'\mathbf{X})^{-1}) \quad (35)$$

where $\hat{\beta} = \text{vec}(\hat{\mathbf{B}}) = \text{vec}((\mathbf{X}'\mathbf{X})^{-1}(\mathbf{X}'\mathbf{Y}))$ is the vectorized OLS estimator of \mathbf{B} and " \otimes " denotes the Kronecker product.¹⁹

The posterior distribution of Σ can be shown to be the inverted-Wishart distribution (the multivariate analog of the inverted-gamma distribution),

$$p(\Sigma | \mathbf{y}, \mathbf{X}) = IW(v^*, \mathbf{S}) \quad (36)$$

where the degrees of freedom parameter is $v^* = T - K + N + 1$ and the scale matrix is $\mathbf{S} = (\mathbf{Y} - \mathbf{X}\hat{\mathbf{B}})'(\mathbf{Y} - \mathbf{X}\hat{\mathbf{B}})$.

A full Bayesian informative prior approach to estimation of the multivariate linear regression model would involve specifying a prior distribution for the regression coefficients, β , and the covariance matrix, Σ . The conjugate prior scenario is invariably the scenario of choice, so as to keep the estimation within analytically manageable boundaries. That scenario consists of a multivariate normal prior for β and inverted-Wishart for Σ .²⁰

KEY POINTS

- To account for estimation risk and to incorporate prior information, regression estimation can be cast in a Bayesian setting.
- Depending on the amount of prior information, diffuse or informative priors can be selected for the regression parameters.
- Under the assumption that the regression innovations are distributed with the normal

distribution, the natural conjugate priors for the regression coefficients and variance are Gaussian and inverted- χ^2 distributions, respectively.

- The case of unequal variances is easily incorporated into the linear regression. Unequal variances may be due to reasons such as structural breaks in time series data or nonhomogeneity in cross-sectional data.

NOTES

1. In order for the inverse matrix in (6) to exist, it is necessary that $\mathbf{X}'\mathbf{X}$ be nonsingular, that is, that the $n \times K$ matrix \mathbf{X} have a rank K (all its columns be linearly independent).

2. The MLE of σ^2 is in fact

$$\hat{\sigma}_{MLE}^2 = \frac{1}{n}(\mathbf{y} - \mathbf{X}\hat{\beta})'(\mathbf{y} - \mathbf{X}\hat{\beta})$$

However, as it is not unbiased, the estimator in (7) is more often employed.

3. In fact, it is possible to describe fully the distribution of β even without knowing its unconditional distribution, by employing a numerical simulation method such as the *Gibbs sampler*, for example, and making inferences on the basis of samples drawn from β 's and σ^2 's posterior distributions.
4. We denote the multivariate scaled, noncentral Student's t distribution with degrees of freedom ν , location parameter vector μ , and scale matrix \mathbf{S} by $t(\nu, \mu, \mathbf{S})$. Its mean and covariance matrix are given, respectively, by μ and $\mathbf{S}^{-1}\nu/(\nu - 2)$.
5. There are two contrasting approaches to prior parameter assertion. The full Bayesian approach calls for specifying the hyperprior parameters independently of the data used for model estimation. The empirical Bayesian approach would use the OLS estimate, $\hat{\beta}$, obtained from the data sample used for estimation, as the value for the hyperprior parameter.
6. The mean and variance of a random variable X distributed with the inverted- χ^2 distribution with parameters ν and c are given,

respectively, by

$$E(X) = \frac{\nu}{\nu - 2}c \quad \text{var}(X) = \frac{2\nu^2}{(\nu - 2)^2(\nu - 4)}c^2$$

7. See Chapter 6 in Rachev et al. (2008) for more details on this shrinkage effect.
8. Denoting the sampling and posterior densities by $f(x|\theta)$ and $p(\theta|x)$, respectively, the predictive density one step ahead is defined as

$$f(x_{+1}|x) = \int f(x_{+1}|\theta)p(\theta|x)d\theta$$

where x is the observed data, θ is the sampling distribution's parameter, and x_{+1} denotes the one-step-ahead realization.

9. Returns on interest-rate instruments and foreign exchange are particularly likely to exhibit structural breaks.
10. See, for example, Wang and Zivot (2000). Chapter 11 in Rachev et al. (2008) discusses the so-called "regime switching" models, in which parameters are allowed to change values according to the state of the world prevailing in a particular period in time.
11. See Chapter 4 in Zellner (1971).
12. See Chapter 5 in Rachev et al. (2008) for details on how to employ numerical simulation methods to tackle inference when no analytical results are available.
13. The standard deviation of the univariate Student's t distribution with degrees-of-freedom parameter ν and scale parameter σ is given by $\sigma\sqrt{\nu/(\nu - 2)}$.
14. Notice that, since the Student's t distribution is unimodal, these (symmetric) intervals are also the highest posterior density intervals.
15. Although the multivariate normal distribution is usually assumed because of its analytical tractability, dependencies among asset returns could be somewhat more complex than what the class of elliptical distributions (to which the normal distribution belongs) is able to describe. Alternative distributional assumptions could be made

at the expense of analytical convenience and occasional substantial estimation problems (especially in high-dimensional settings). A more flexible way of dependence modeling is provided through the use of copulas. Some types of copulas could also suffer from estimation problems, especially in large-scale applications.

16. For applications to portfolio construction, see Chapters 6 through 9 in Rachev et al. (2008).
17. The expression in the exponent in (33) could also be written as

$$-\frac{1}{2}\text{tr}(\mathbf{Y} - \mathbf{XB})'(\mathbf{Y} - \mathbf{XB})\Sigma^{-1},$$

where "tr" denotes the trace operator, which sums the diagonal elements of a square matrix.

18. As in the univariate case, we assume independence between (the elements of) \mathbf{B} and Σ .
19. The Kronecker product is an operator for direct multiplication of matrices (which are not necessarily compatible). For two matrices, A of size $m \times n$ and B of size $p \times q$, the Kronecker product is defined as

$$A \otimes B = \begin{pmatrix} a_{1,1}B & a_{1,2}B & \dots & a_{1,n}B \\ \dots & \dots & \dots & \dots \\ a_{m,1}B & a_{m,2}B & \dots & a_{m,n}B \end{pmatrix}$$

resulting in an $mp \times nq$ block matrix.

20. See Chapters 6 and 7 of Rachev et al. (2008) for further details in the context of portfolio selection.

Abstract: Empirical evidence abounds that asset returns exhibit characteristics such as volatility clustering, asymmetry, and heavy-tailedness. Volatility clustering describes the tendency of returns to alternate between periods of high volatility and low volatility. In addition, volatility responds asymmetrically to positive and negative return shocks—it tends to be higher when the market falls than when it rises. The nonconstancy of volatility has been suggested as an underlying reason for returns' fat tails. Volatility models attempt to systematically explain these stylized facts about asset returns. The Bayesian methodology offers distinct advantages over the classical framework in estimating volatility models. Parameter restrictions, such as stationarity restriction, are notoriously difficult to handle within the frequentist setting and straightforward to implement in the Bayesian one. The MCMC numerical simulation methods facilitate greatly the estimation of complex volatility models, such as Markov-switching volatility models.

Generalized autoregressive conditional heteroskedastic (GARCH) models are used in financial modeling to provide a measure of volatility that could be employed in portfolio selection, risk management, and derivatives pricing. In this entry, we focus on the Bayesian treatment of

GARCH model estimation. Our discussion of prior distributions' choice and posterior analysis is developed around an example where the data are assumed to follow the Student's t distribution. We then introduce a Bayesian approach to Markov-switching GARCH models

and explain in detail the steps one could use to estimate this important extension of the simple GARCH model.

BAYESIAN ESTIMATION OF THE GARCH(1,1) MODEL

Volatility is a forward-looking concept. It is the variance of the yet unrealized asset return, conditional on all relevant, available information. Denote by r_t the asset return at time t and by F_{t-1} the set of information available up to time $t - 1$. The information set includes, for example, past asset returns and past trading volume. The return's dynamics can be described as follows:

$$r_t = \mu_{t|t-1} + \sigma_{t|t-1}\epsilon_t \quad (1)$$

where

- $\mu_{t|t-1}$ is the return's conditional expectation at time t ,
- $\sigma_{t|t-1}$ is the return's conditional volatility at time t ,
- ϵ_t is a white noise process (a sequence of independent and identically distributed random variables with zero mean and variance of one).

The aim of volatility models is to specify the dynamics of $\sigma_{t|t-1}$. Autoregressive conditional heteroskedastic (ARCH)-type models describe the conditional volatility at time t as a deterministic function of (attribute of) past squared returns. That is, volatility at time t can be uniquely determined at time $t - 1$. The volatility updating expression of a GARCH(1,1) process is given by

$$\sigma_{t|t-1}^2 = \omega + \alpha u_{t-1}^2 + \beta \sigma_{t-1|t-2}^2 \quad (2)$$

where $u_t = \sigma_{t|t-1}\epsilon_t$. The model parameters are restricted to be nonnegative— $\omega > 0$, $\alpha \geq 0$, and $\beta \geq 0$ —in order to ensure that the conditional variance is positive for all values of the white noise process, ϵ_t . Additionally, the requirement for stationarity imposes the constraint that the sum $\alpha + \beta$ is smaller than one.

Estimation of the model parameters is usually performed by likelihood maximization. Since the return at time t , r_t , depends on $\sigma_{t|t-1}$ and through it on the conditional volatilities in all previous periods, the unconditional density of the return is not available in closed form (it is a mixture of densities depending on the dynamics of $\sigma_{t|t-1}^2$). Therefore, the likelihood function of the GARCH(1,1) model is expressed as the product of the conditional densities of r_t for each period t , $t = 1, 2, \dots, T$.

Given F_0 , the likelihood function $L(\boldsymbol{\theta} | r_1, r_2, \dots, r_T, F_0)$ is written as¹

$$L(\boldsymbol{\theta} | \mathbf{r}, F_0) = f(r_1 | \boldsymbol{\theta}, F_0) f(r_2 | \boldsymbol{\theta}, F_1) \dots f(r_T | \boldsymbol{\theta}, F_{T-1}) \quad (3)$$

where $\mathbf{r} = (r_1, r_2, \dots, r_T)$. Due to the form of the likelihood function, posterior estimation is performed, without exception, numerically. This, on the other hand, implies that few, if any, restrictions exist on the choice of prior distributions, when estimation is cast in a Bayesian setting.

In this entry, our focus is on the Student's t distributional assumption for the return disturbances, in an attempt to reflect the empirically observed heavy-tailedness of returns. This comes at the expense of only a marginal increase in complexity (compared to estimation of a model with normally distributed disturbances). The two numerical simulation methods we employ to simulate the posterior distribution of the vector of model parameters, $\boldsymbol{\theta}$, are the Metropolis-Hastings algorithm and the Gibbs sampler.²

Our focus is the model of returns in (1) with a modification. We assume that the return mean is unconditional and equal to zero. That is, we define our parameter vector as $\boldsymbol{\theta} = (\omega, \alpha, \beta, \nu)$

Distributional Setup

Next, we outline the general setup we use in our Bayesian estimation of the GARCH(1,1) model. We modify this setup in the second half of the entry, where we discuss regime switching.

Likelihood Function

Assuming that ϵ_t is distributed with a Student's t distribution with ν degrees of freedom, we write the likelihood function for the model's parameters as

$$L(\boldsymbol{\theta} | \mathbf{r}, F_0) \propto \prod_{t=1}^T \left[(\sigma_{t|t-1}^2)^{-1} \left(1 + \frac{1}{\nu} \frac{r_t^2}{\sigma_{t|t-1}^2} \right)^{-\frac{\nu+1}{2}} \right] \quad (4)$$

where σ_0^2 is considered as a known constant, for simplicity. Under the Student's t assumption for ϵ_t , the conditional volatility at time t is given by

$$\frac{\nu}{\nu - 2} \sigma_t^2$$

for ν greater than 2.

Prior Distributions

For simplicity, assume that the conditional variance parameters have uninformative diffuse prior distributions over their respective ranges,³

$$\pi(\omega, \alpha, \beta) \propto 1 I_{\{\theta_G\}} \quad (5)$$

where $I_{\{\theta_G\}}$ is an indicator function reflecting the constraints on the conditional variance parameters,

$$I_{\{\theta_G\}} = \begin{cases} 1 & \text{if } \omega > 0, \alpha > 0, \text{ and } \beta > 0, \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

The choice of prior distribution for the degrees-of-freedom parameter, ν , requires more care. Bauwens and Lubrano (1998) show that if a diffuse prior for ν is asserted on the interval $[0, \infty)$, the posterior distribution of ν is not proper (its right tail does not decay quickly enough, so that the posterior does not integrate to 1). Therefore, the prior for ν needs to be proper. Geweke (1993a) advocates the use of an exponential prior distribution with density given by

$$\pi(\nu) = \lambda \exp(-\nu\lambda) \quad (7)$$

The mean of the exponential distribution is given by $1/\lambda$. The parameter λ can thus be uniquely determined from the prior intuition about ν 's mean. Another prior option for ν is a uniform prior over an interval $[0, M]$, where

M is some finite number. Empirical research indicates that the degrees-of-freedom parameter calibrated from financial returns data (especially of daily and higher frequency) is usually less than 20, so the upper bound, M , of ν 's range could be fixed at 20, for instance. Bauwens and Lubrano propose a third prior for ν —the upper half of a Cauchy distribution centered around zero. In our discussion, we adopt the exponential prior distribution for ν in (7).

Posterior Distributions

Given the distributional assumptions above, the posterior distribution of $\boldsymbol{\theta}$ is written as

$$\begin{aligned} p(\boldsymbol{\theta} | \mathbf{r}, F_0) &\propto \prod_{t=1}^T \left[(\sigma_{t|t-1}^2)^{-1} \left(1 + \frac{1}{\nu} \frac{r_t^2}{\sigma_{t|t-1}^2} \right)^{-\frac{\nu+1}{2}} \right] \\ &\times \exp(-\nu\lambda) \\ &\times I_{\{\theta_G\}} \end{aligned} \quad (8)$$

The restrictions on ω , α , and β are enforced during the sampling procedure by rejecting the draws that violate them. Stationarity can also be imposed and dealt with in the same way.

As evident from the expression in (8), the joint posterior density does not have a closed form. Posterior numerical simulations are facilitated if one employs a specific representation of the Student's t distribution—a scale mixture of normal distributions. We explain this representation before we move on to the discussion of sampling algorithms.

Mixture of Normals Representation of the Student's t Distribution

Suppose that return r_t is distributed with the Student's t distribution with ν degrees of freedom, scale parameter σ , and location parameter μ . This distributional assumption can be represented as a scale mixture of normal distributions, given by⁴

$$r_t | \mu_t, \sigma_t, \eta_t \sim N \left(\mu_t, \frac{\sigma_t}{\eta_t} \right) \quad (9)$$

where η , the so-called “mixing variable,” has the gamma distribution,

$$\eta_t | \nu \sim \text{Gamma}\left(\frac{\nu}{2}, \frac{\nu}{2}\right), \quad \text{for } t = 1, \dots, T \quad (10)$$

The benefit of employing this representation is increased tractability of the posterior distribution because the nonlinear expression for the model’s likelihood in (4) is linearized. Sampling from the conditional distributions of the remaining parameters is thus greatly facilitated. This comes at the expense of T additional model parameters, $\boldsymbol{\eta} = (\eta_1, \dots, \eta_T)'$, whose conditional posterior distribution needs to be simulated as well.⁵

Under this Student’s t representation, the parameter vector, $\boldsymbol{\theta}$, is transformed to⁶

$$\boldsymbol{\theta} = (\omega, \alpha, \beta, \nu, \boldsymbol{\eta}') \quad (11)$$

The log-likelihood function for $\boldsymbol{\theta}$ is simply the normal log-likelihood,

$$\begin{aligned} \log(L(\boldsymbol{\theta} | \mathbf{r}, F_0)) &= \text{const} - \frac{1}{2} \sum_{t=1}^T \\ &\times \left[\log(\sigma_{t|t-1}^2) - \log(\eta_t) + \frac{\eta_t r_t^2}{\sigma_{t|t-1}^2} \right] \end{aligned} \quad (12)$$

The posterior distribution of $\boldsymbol{\theta}$ has an additional term reflecting the mixing variables’ distribution. The log-posterior distribution is written as

$$\begin{aligned} \log(p(\boldsymbol{\theta} | \mathbf{r}, F_0)) &= \text{const} - \frac{1}{2} \sum_{t=1}^T \\ &\times \left[\log(\sigma_{t|t-1}^2) - \log(\eta_t) + \frac{\eta_t r_t^2}{\sigma_{t|t-1}^2} \right] \\ &+ \frac{T\nu}{2} \log\left(\frac{\nu}{2}\right) - T \log\left(\Gamma\left(\frac{\nu}{2}\right)\right) \\ &+ \left(\frac{\nu}{2} - 1\right) \sum_{t=1}^T \log(\eta_t) \\ &- \frac{\nu}{2} \sum_{t=1}^T (\eta_t) - \nu\lambda \end{aligned} \quad (13)$$

$$\text{for } \omega > 0, \quad \alpha \geq 0, \quad \text{and } \beta \geq 0$$

Next, we discuss some strategies for simulating the posterior in (13).

Posterior Simulations with the Metropolis-Hastings Algorithm

The Metropolis-Hastings (M-H) algorithm could be implemented in two ways. The first way is by sampling the whole parameter vector, $\boldsymbol{\theta}$, from a proposal distribution (usually a multivariate Student’s t distribution) centered on the posterior mode and scaled by the negative inverse Hessian (evaluated at the posterior mode).⁷ The second way is by employing a sampling scheme in which the parameter vector is updated component by component. Here, we focus on the latter M-H implementation.

Consider the decomposition of the parameter vector $\boldsymbol{\theta}$ into three components, $\boldsymbol{\theta} = (\boldsymbol{\theta}_G, \nu, \boldsymbol{\eta}')$, where $\boldsymbol{\theta}_G = (\omega, \alpha, \beta)$. We would like to employ a scheme of sampling consecutively from the conditional posterior distributions of the components, given, respectively, by $p(\boldsymbol{\theta}_G | \boldsymbol{\eta}, \nu, \mathbf{r}, F_0)$, $p(\nu | \boldsymbol{\theta}_G, \boldsymbol{\eta}, \mathbf{r}, F_0)$, and $p(\boldsymbol{\eta} | \boldsymbol{\theta}_G, \nu, \mathbf{r}, F_0)$. The scale mixture of normals representation of a Student’s t distribution allows us to recognize the conditional posterior distribution of the last component, $\boldsymbol{\eta}$, as a standard distribution. For the first two components, $\boldsymbol{\theta}_G$ and ν , whose posterior distributions are not of standard form, we offer two posterior simulation approaches and mention alternatives that have been suggested in the literature.

Conditional Posterior Distribution for $\boldsymbol{\eta}$

The full conditional posterior distribution for the (independently-distributed) mixing parameters, η_t , $t = 1, \dots, T$, can be shown to be a gamma distribution,

$$\begin{aligned} p(\eta_t | \boldsymbol{\theta}_G, \nu, \mathbf{r}, F_0) \\ = \text{Gamma}\left(\frac{\nu + 1}{2}, \frac{r_t^2}{2\sigma_{t|t-1}^2} + \frac{\nu}{2}\right) \end{aligned} \quad (14)$$

Conditional Posterior Distribution for ν

It can be seen from (13) that the conditional posterior distribution of the degrees-of-freedom parameter, ν , does not have a standard form.

The kernel of the posterior distribution is given by the expression,

$$p(v | \theta_G, \eta, r, F_0) \propto \Gamma\left(\frac{v}{2}\right)^{-T} \left(\frac{v}{2}\right)^{\frac{Tv}{2}} \exp(v\lambda^*) \quad (15)$$

where

$$\lambda^* = \frac{1}{2} \sum_{t=1}^T (\log(\eta_t) - \eta_t) - \lambda \quad (16)$$

Geweke (1993b) describes a rejection sampling approach that could be employed to simulate draws from the conditional posterior distribution of v in (15). In this entry, we employ a sampling algorithm called the griddy Gibbs sampler. The appendix provides details on it.

Proposal Distribution for θ_G

The kernel of θ_G 's log-posterior distribution is given by the expression,

$$\begin{aligned} &\log(p(\theta_G | \theta_{-\theta_G}, r, F_0)) \\ &= \text{const} - \frac{1}{2} \sum_{t=1}^T \left[\log(\sigma_{t|t-1}^2) + \frac{\eta_t r_t^2}{\sigma_{t|t-1}^2} \right] \\ &\text{for } \omega > 0, \quad \alpha \geq 0, \quad \text{and } \beta \geq 0 \end{aligned}$$

where $\sigma_{t|t-1}^2, t = 1, \dots, T$, is a function of θ_G .

We specify a Student's t proposal distribution for θ_G , centered on the posterior mode of θ_G and scaled by the negative inverse Hessian of the posterior kernel, evaluated at the posterior mode. Other approaches for posterior simulation, for example, the griddy Gibbs sampler, could be employed as well. (In this case, the components of θ_G would be sampled separately.)

Having determined the full conditional posterior distribution η , as well as a proposal distribution for θ_G and a sampling scheme for v , implementing a hybrid M-H algorithm is straightforward. Its steps are as follows. At iteration m of the algorithm,

- Draw an observation, θ_G^* , of the vector of conditional variance parameters, θ_G , from its proposal distribution.

- Check whether the positivity (and stationarity) parameter restrictions on the components of θ_G are satisfied. If not, draw θ_G^* repeatedly until they are satisfied.
- Compute the acceptance probability

$$\begin{aligned} &a(\theta_G^*, \theta_G^{(t-1)}) \\ &= \min \left\{ 1, \frac{p(\theta_G^* | \mathbf{y}) / q(\theta_G^* | \theta_G^{(t-1)})}{p(\theta_G^{(t-1)} | \mathbf{y}) / q(\theta_G^{(t-1)} | \theta_G^*)} \right\} \quad (17) \end{aligned}$$

where $p(\theta_G | \mathbf{y})$ is θ_G 's posterior distribution and $q(\theta_G | \cdot)$ is θ_G 's proposal distribution. The previous draw of the parameter vector is given by θ_G^{t-1} . Accept or reject the candidate draw θ_G^* with probability $a(\theta_G^*, \theta_G^{(t-1)})$.

- Draw an observation, $\eta^{(m)}$, from the full conditional posterior distribution, $p(\eta_t | \theta_G^{(m)}, r, F_0)$, in (14)
- Draw an observation, $v^{(m)}$, from its conditional posterior distribution with kernel in (15) using the griddy Gibbs sampler as explained in the appendix.

At each iteration of the sampling algorithm, the sampling strategy described above produces a large output consisting of the draws from the model parameters and the T mixing variables, η . However, since the role of the mixing parameters is only auxiliary and their conditional distribution is of no interest, at any iteration of the algorithm above one needs to store only the latest draw of η (as well as the draws of v and θ_G , of course).

In the simple GARCH model discussed now, it is implicitly assumed that expression (2) describes the volatility process during the whole sample period and (at least) in the short run after the end of the sample. That is, the parameters of the model are unchanged throughout. It is not inconceivable, however, that the volatility dynamics differ in different periods. Then, volatility forecasts produced by a simple (single-regime) model are likely to overestimate volatility during periods of low volatility and underestimate it during periods of

high volatility. In the next section, we discuss a class of models extending the simple GARCH(1,1) model, which could potentially provide more accurate volatility forecasting power. Regime-switching models incorporate the possibility that the dynamics of the volatility process evolves through different states of nature, which we call regimes.

MARKOV-SWITCHING GARCH MODELS

The *Markov-switching* (MS) models, introduced by Hamilton (1989), provide maximal flexibility in modeling transitions of the volatility dynamics across regimes. They form the class of the so-called endogenous regime-switching models in which transitions between states of nature are governed by parameters estimated within the model; the number of transitions is not specified a priori, unlike the number of states. Each volatility state could be revisited multiple times.⁸ In our discussion below, we use the terms “state” and “regime” interchangeably.

Different approaches to introducing regime changes in the GARCH process have been proposed in the empirical finance literature. Hamilton and Susmel (1994) incorporate a regime-dependent parameter, g_{S_t} , into the standard deviation (scale) of the returns process,

$$r_t = \mu_{t|t-1} + \sqrt{g_{S_t}} \sigma_{t|t-1} \epsilon_t$$

where S_t denotes period t 's regime. Another option, pursued by Cai (1994), is to include a regime-dependent parameter as part of the constant in the conditional variance equation,

$$\sigma_{t|t-1}^2 = (\omega + g_{S_t}) + \sum_{p=1}^P \alpha_p u_{t-p}^2$$

Both Hamilton and Susmel (1994) and Cai (1994) model the dynamics of the conditional variance with an ARCH process. The reason, as explained further below, is that when GARCH term(s) are present in the process, the regime-

dependence makes the likelihood function analytically intractable.

The most flexible approach to introducing regime-dependence is to allow all parameters of the conditional variance equation to vary across regimes. That approach is suggested by Henneke, Rachev, Fabozzi, and Nikolov (2011) who model jointly the conditional mean as an ARMA(1,1) process in a Bayesian estimation setting.⁹ The implication for the dynamics of the conditional variance is that the manner in which the variance responds to past return shocks and volatility levels changes across regimes. For example, high-volatility regimes could be characterized by “hyper-sensitivity” of asset returns to return shocks and high volatility in one period could have a more lasting effect on future volatilities compared to low-volatility regimes. This would call for a different relationship between the parameters α and β in different regimes.

In this section, we discuss the estimation method of Henneke, Rachev, Fabozzi, and Nikolov (2011), with some modifications.

Preliminaries

Suppose that there are three states the conditional volatility can occupy, denoted by $i, i = 1, 2, 3$. We could assign economic interpretation to them by labeling them “a low-volatility state,” “a normal-volatility state,” and “a high-volatility state.” Denote by π_{ij} the probability of a transition from state i to state j . The transition probabilities, π_{ij} , could be arranged in the transition probability matrix, Π ,

$$\Pi = \begin{pmatrix} \pi_{11} & \pi_{12} & \pi_{13} \\ \pi_{21} & \pi_{22} & \pi_{23} \\ \pi_{31} & \pi_{32} & \pi_{33} \end{pmatrix} \quad (18)$$

such that the probabilities in each row sum up to 1. The Markov property (central to model estimation, as we will see below) that lends its name to the MS models concerns the memory of the process—which volatility regime the system visits in a given period depends only on the

regime in the previous period. Analytically, the Markov property is expressed as

$$P(S_t | S_{t-1}, S_{t-2}, \dots, S_1) = P(S_t | S_{t-1}) \quad (19)$$

Each row of Π in (18) represents the three-dimensional conditional probability distribution of S_t , conditional on the regime realization in the previous period, S_{t-1} . We say that $\{S_t\}_{t=1}^T$ is a three-dimensional (discrete-time) Markov chain with transition matrix, Π .

In the regime-switching GARCH(1,1) setting, the expression for the conditional variance dynamics becomes

$$\sigma_{t|t-1}^2 = \omega(S_t) + \alpha(S_t)u_{t-1}^2 + \beta(S_t)\sigma_{t-1|t-2}^2 \quad (20)$$

For each period t ,

$$(\omega(S_t), \alpha(S_t), \beta(S_t)) = \begin{cases} (\omega_1, \alpha_1, \beta_1) & \text{if } S_t = 1, \\ (\omega_2, \alpha_2, \beta_2) & \text{if } S_t = 2, \\ (\omega_3, \alpha_3, \beta_3) & \text{if } S_t = 3 \end{cases}$$

The presence of the GARCH component in (20) complicates the model estimation substantially. To see this, notice that, via $\sigma_{t-1|t-2}^2$, the current conditional variance depends on the conditional variances from all preceding periods and, therefore, on the whole unobservable sequence of regimes up to time t . A great number of regime paths could lead to the particular conditional variance at time t (the number of possible regime combinations grows exponentially with the number of time periods), rendering classical estimation very complicated. For that reason, the early treatments of MS models include only an ARCH component in the conditional variance equation. The MCMC methodology, however, copes easily with the specification in (20), as we will see below.

We adopt the same return decomposition as in (1)—with the conditional mean set to zero—and note that, given the regime path, (20) represents the same conditional variance dynamics as a simple GARCH(1,1) process. We return to this point again further below when we discuss estimation of that MS GARCH(1,1) model.

Next, we outline the prior assumptions for the MS GARCH(1,1) model.

Prior Distributional Assumptions

The parameter vector of the MS GARCH(1,1) model, specified by (1), (20), and the Markov chain $\{S_t\}_{t=1}^T$, is given by

$$\theta = (\eta', \nu, \theta_{G,1}, \theta_{G,2}, \theta_{G,3}, \pi_1, \pi_2, \pi_3, S) \quad (21)$$

where, for $i = 1, 2, 3$,

$$\theta_{G,i} = (\omega_i, \alpha_i, \beta_i) \quad \text{and} \quad \pi_i = (\pi_{i1}, \pi_{i2}, \pi_{i3})$$

and S is the regime path for all periods,

$$S = (S_1, \dots, S_T)$$

Our prior specifications for η and ν remain unchanged from our earlier discussion: The scale-mixture-of-normals mixing parameters, η , and the degrees-of-freedom parameter, ν , are not affected by the regime specification in the MS GARCH(1,1) model. We assert prior distributions for the vector of conditional variance parameters, $\theta_{G,i}$, under each regime, i , and a prior distribution for each triple of transition probabilities π_i , $i = 1, 2, 3$.

Prior Distributions for $\theta_{G,i}$

To reflect our prior intuition about the effect the three regimes have on the conditional variance parameters, we assert proper normal priors for $\theta_{G,i}$, $i = 1, 2, 3$.

$$\theta_{G,i} \sim N(\mu_i, \Sigma_i) I_{\{\theta_{G,i}\}} \quad (22)$$

where the indicator function, $I_{\{\theta_{G,i}\}}$, is given in (6). As explained earlier in the entry, the parameter constraints are imposed during the implementation of the sampling algorithm.

Prior Distribution for π_i

A convenient prior for the probability parameter in a binomial experiment is the beta distribution.¹⁰ The analogue of the beta distribution in the multivariate case is the so-called Dirichlet distribution.¹¹ Therefore, we specify a Dirichlet prior distribution for each triple of transition probabilities, $i = 1, 2, 3$,

$$\pi_i \sim \text{Dirichlet}(a_{i1}, a_{i2}, a_{i3}) \quad (23)$$

To elicit the prior parameters, a_{ij} , $i, j = 1, 2, 3$, it is sufficient that one express prior intuition about the expected value of each of the transition probabilities in a triple, then solve the system equations for a_{ij} .

Estimation of the MS GARCH Model

The evolution of volatility in the MS GARCH model is governed by the realizations of the unobservable (latent) regime variable, S_t , $t = 1, \dots, T$. Hence, the discrete-time Markov chain, $\{S_t\}_{t=1}^T$ is also called a hidden Markov process. Earlier, we briefly discussed that the presence of the hidden Markov process creates a major estimation difficulty in the classical setting. The Bayesian methodology, in contrast, deals with the latent-variable characteristic in an easy and natural way: The latent variable is simulated together with the model parameters. In other words, the parameter space is augmented with S_t , $t = 1, \dots, T$, in much the same way as the vector of mixing variables, η , was added to the parameter space in estimating the Student's t GARCH(1,1) model. The distribution of S is a multinomial distribution,

$$\begin{aligned} p(S|\boldsymbol{\pi}) &= \prod_{t=1}^{T-1} p(S_{t+1}|S_t, \boldsymbol{\pi}) \\ &= \pi_{11}^{n_{11}} \pi_{12}^{n_{12}} \dots \pi_{32}^{n_{32}} \pi_{33}^{n_{33}} \\ &= \pi_{11}^{n_{11}} \pi_{12}^{n_{12}} (1 - \pi_{11} - \pi_{12})^{n_{13}} \dots \\ &\quad \pi_{32}^{n_{32}} (1 - \pi_{31} - \pi_{32})^{n_{33}} \end{aligned} \quad (24)$$

where n_{ij} denotes the number of times the chain transitions from state i to state j during the span of period 1 through period T . The first equality in (24) follows from the Markov property of $\{S_t\}_{t=1}^T$.

Based on our discussion of the Student's t GARCH(1,1) model and the hidden Markov process, as well as the prior distributional assumptions for $\boldsymbol{\pi}_i$ and $\boldsymbol{\theta}_{G,i}$, $i = 1, 2, 3$, the joint log-posterior distribution of the MS GARCH(1,1) model's parameter vector $\boldsymbol{\theta}$ is

given by

$$\begin{aligned} \log(p(\boldsymbol{\theta} | \mathbf{r}, F_0)) &= \text{const} \\ &- \frac{1}{2} \sum_{t=1}^T \left[\log(\sigma_{t|t-1}^2) + \log(\eta_t) + \frac{\eta_t r_t^2}{\sigma_{t|t-1}^2} \right] \\ &- \frac{1}{2} \sum_{i=1}^3 (\boldsymbol{\theta}_{G,i} - \boldsymbol{\mu}_i)' \boldsymbol{\Sigma}_i^{-1} (\boldsymbol{\theta}_{G,i} - \boldsymbol{\mu}_i) I_{\{S(t)=i\}} \\ &+ \frac{T\nu}{2} \log\left(\frac{\nu}{2}\right) - T \log\left(\Gamma\left(\frac{\nu}{2}\right)\right) + \left(\frac{\nu}{2} - 1\right) \\ &\times \sum_{t=1}^T \log(\eta_t) - \frac{\nu}{2} \sum_{t=1}^T \eta_t - \nu\lambda \\ &+ \sum_{i=1}^3 \sum_{j=1}^3 (a_{ij} + n_{ij} - 1) \log(\pi_{ij}) \end{aligned} \quad (25)$$

for $\omega_i > 0$, $\alpha_i \geq 0$, and $\beta_i \geq 0$

Although (25) looks very similar to the joint log-posterior in (13), there is a crucial difference. The model's log-likelihood (given by the right-hand-side term in the first line of (25)) depends on the whole sequence of regimes, S . Conditional on S , however, it is the same log-likelihood as in (12). We will exploit this fact in constructing the posterior simulation algorithm as an extension of the algorithm for the Student's t GARCH(1,1) model estimation.

We now outline the posterior results for $\boldsymbol{\pi}_i$, S , and $\boldsymbol{\theta}_{G,i}$. The posterior results for the degrees-of-freedom parameter, ν , and the mixing variables, $\boldsymbol{\eta}$, remain unchanged from our earlier discussion.

Conditional Posterior Distribution of $\boldsymbol{\pi}_i$

The conditional log-posterior distribution of the vector of transition probabilities, $\boldsymbol{\pi}_i$, $i = 1, 2, 3$, is given by

$$\begin{aligned} \log(p(\boldsymbol{\pi}_i | \mathbf{r}, \boldsymbol{\theta}_{-\boldsymbol{\pi}_i})) &= \text{const} \\ &+ \sum_{j=1}^3 (a_{ij} + n_{ij} - 1) \log(\pi_{ij}) \\ &\text{for } i = 1, 2, 3 \end{aligned} \quad (26)$$

where $\boldsymbol{\theta}_{-\boldsymbol{\pi}_i}$ denotes the vector of all parameters except $\boldsymbol{\pi}_i$. The expression in (26) is readily

recognized as the logarithm of the kernel of a Dirichlet distribution with parameters $(a_{i1} + n_{i1}, a_{i2} + n_{i2}, a_{i3} + n_{i3})$. The parameters a_{ij} are specified a priori, while the parameters n_{ij} can be determined by simply counting the number of times the Markov chain, $\{S_t\}_{t=1}^T$, transitions from i to j .

Sampling from the Dirichlet distribution in (26) is accomplished easily in the following way.¹² For each $i, i = 1, 2, 3$,

(1) sample three independent observations,

$$y_{i1} \sim \chi^2_{2(a_{i1}+n_{i1})}, y_{i2} \sim \chi^2_{2(a_{i2}+n_{i2})},$$

$$y_{i3} \sim \chi^2_{2(a_{i3}+n_{i3})}$$

(2) set

$$\pi_{i1} = \frac{y_{i1}}{\sum_{k=1}^3 y_{ik}}, \quad \pi_{i2} = \frac{y_{i2}}{\sum_{k=1}^3 y_{ik}},$$

$$\pi_{i3} = \frac{y_{i3}}{\sum_{k=1}^3 y_{ik}}$$

Conditional Posterior Distribution of S

In the three-regime switching setup of this entry, the number of regime paths that could have potentially generated S_T , the regime in the final period, is 3^T . The level of complexity makes it impossible to obtain a draw of the whole $1 \times T$ vector, S , at once. Instead, its components can be drawn one at a time, in a T -step procedure. In other words, at each step, we sample from the full conditional posterior density of S_t given by

$$p(S_t = i | r, \theta_{-S}, S_{-t}) \quad (27)$$

where θ_{-S} is the parameter vector in (21) excluding S and S_{-t} is the regime path excluding the regime at time t . Applying the rules of conditional probability, $p(S_t = i | r, \theta_{-S_t})$ is written as

$$p(S_t = i | r, \theta_{-S}, S_{-t}) = \frac{p(S_t = i, S_{-t}, r | \theta_{-S})}{p(S_{-t}, r | \theta_{-S})}$$

$$= \frac{p(r | \theta_{-S}, S_{-t}, S_t = i) p(S_t = i, S_{-t} | \theta_{-S})}{p(S_{-t}, r | \theta_{-S})} \quad (28)$$

The first term in the numerator, $p(r | \theta_{-S}, S_{-t}, S_t = i)$, is simply the model's likelihood evaluated at a given regime path, in which $S_t = i$. The second term in the numerator, $p(S_t = i, S_{-t})$, is given, by the Markov property, by

$$p(S_t = i, S_{-t} | \theta_{-S}) = p(S_t = i, S_{t-1} = j, S_{t+1} = k | \theta_{-S})$$

$$= \pi_{j,i} \pi_{i,k} \quad (29)$$

while the denominator in (28) is expressed as

$$p(S_{-t}, r | \theta_{-S}) = \sum_{s=1}^3 p(S_t = s, S_{-t}, r | \theta_{-S}) \quad (30)$$

Using (28), (29), and (30), we obtain the conditional posterior distribution of S_t as

$$p(S_t = i | r, \theta_{-S}, S_{-t}) = \frac{p(r | \theta_{-S}, S_{-t}, S_t = i) \pi_{j,i} \pi_{i,k}}{\sum_{s=1}^3 p(r | \theta_{-S}, S_{-t}, S_t = s) \pi_{j,s} \pi_{s,k}} \quad (31)$$

for $i = 1, 2, 3$. An observation, S_t^* , from the conditional density in (31) is obtained in the following way:

- Compute the probability in (31) for $i = 1, 2, 3$.
- Split the interval $(0, 1)$ into three intervals of lengths proportional to the probabilities in step (1).
- Draw an observation, u , from the uniform distribution $U[0, 1]$.
- Depending on which interval u falls into, set $S_t^* = i$.

To draw the regime path, $S^{(m)}$, at the m th iteration of the posterior simulation algorithm,

- Draw $S_1^{(m)}$ from $p(S_1 | r, \theta_{-S_1})$ in (31). Update $S^{(m)}$ with $S_1^{(m)}$.
- For $t = 2, \dots, T$, draw $S_t^{(m)}$ from $p(S_t | r, \theta_{-S_t})$ in (31). Update $S^{(m)}$ with $S_t^{(m)}$.

Proposal Distribution for $\theta_{G,i}$

The posterior distribution of the vector of conditional variance parameters is not available in

closed form because of the regime dependence of the conditional variance. Since in the regime-switching setting we adopted informative prior distributions for $\theta_{G,i}$, $i = 1, 2, 3$, the kernel of the conditional log-posterior distribution is a bit different from the one in (17) and is given by

$$\begin{aligned} \log(p(\theta_{G,i} | \theta_{-\theta_{G,i}}, r, F_0)) &= \text{const} \\ &- \frac{1}{2} \sum_{t=1}^T \left[\log(\sigma_{t|t-1}^2) + \log(\eta_t) + \frac{\eta_t r_t^2}{\sigma_{t|t-1}^2} \right] \\ &- \frac{1}{2} \sum_{i=1}^3 (\theta_{G,i} - \mu_i)' \Sigma_i^{-1} (\theta_{G,i} - \mu_i) I_{\{S_t=i\}}, \end{aligned} \quad (32)$$

$$\text{for } \omega > 0, \quad \alpha \geq 0, \quad \beta \geq 0, \quad \text{and} \\ i = 1, 2, 3$$

For a given regime path, S , the only difference between the earlier posterior kernel and (32) is the term reflecting the informative prior of $\theta_{G,i}$. Therefore, specifying a proposal distribution for $\theta_{G,i}$ is in no way different from the approach in the single-regime Student's t GARCH(1,1) setting.

Sampling Algorithm for the Parameters of the MS GARCH (1,1) Model

The sampling algorithm for the MS GARCH(1,1) model parameters consists of the following steps. At iteration m ,

- Draw $\pi_i^{(m)}$ from its posterior density in (26), for $i = 1, 2, 3$.
- Draw $S^{(m)}$ from (31).
- Draw $\eta^{(m)}$ from (14).
- Draw $\nu^{(m)}$ from (15).
- Draw $\theta_{G,i}^*$, $i = 1, 2, 3$, from the proposal distribution, as explained earlier.
- Check whether the parameter restrictions on the components of $\theta_{G,i}$ are satisfied; if not, draw $\theta_{G,i}^*$ repeatedly, until they are satisfied.
- Compute the acceptance probability in (17) and accept or reject $\theta_{G,i}^*$ for $i = 1, 2, 3$.

The parameter vector, θ , is updated as new components are drawn. The steps above are repeated a large number of times until convergence of the algorithm.

APPENDIX: THE GRIDDY GIBBS SAMPLER

Implementation of the Gibbs sampler requires that parameters' conditional posterior distributions be known. Sometimes, however, the conditional posterior distributions have no closed forms. In these cases, a special form of the Gibbs sampler, called the griddy Gibbs sampler, can be employed whereby the (univariate) conditional posterior densities are evaluated on grids of parameter values. The griddy Gibbs sampler, developed by Ritter and Tanner (1992), is a combination of the ordinary Gibbs sampler and a numerical routine. In this appendix, we illustrate the griddy Gibbs sampler with the posterior distribution of the degrees-of-freedom parameter, ν .

Recall the expression for the kernel of ν 's conditional log-posterior distribution,

$$\begin{aligned} \log(p(\nu | \theta_{-\nu}, r, F_0)) &= \text{const} \\ &+ \frac{T\nu}{2} \log\left(\frac{\nu}{2}\right) - T \log\left(\Gamma\left(\frac{\nu}{2}\right)\right) \\ &+ \left(\frac{\nu}{2} - 1\right) \sum_{t=1}^T \log(\eta_t) - \frac{\nu}{2} \sum_{t=1}^T \eta_t - \nu\lambda. \end{aligned} \quad (33)$$

The griddy Gibbs sampler approach to drawing from the conditional posterior distribution of ν is to recognize that at iteration m we can treat the latest draws of the remaining parameters as the known parameter values. Therefore, we can evaluate numerically the conditional posterior density of ν on a grid of its admissible values. The support of ν is the positive part of the real line. However, a reasonable range for the values of ν in an application to asset returns could be (2, 30).¹³

Drawing from the Conditional Posterior Distribution of ν

Denote the equally-spaced grid of values for ν by $(\nu_1, \nu_2, \dots, \nu_J)$. We outline the steps for drawing from ν 's conditional posterior distribution at iteration m of the sampling algorithm. Denote the most recent draws of the remaining model parameters by $\theta_{-\nu}^{(m-1)}$. (Note that this notation is not entirely precise since some of the parameters might have been updated last during the m th iteration of the sampler but before ν .)

- Compute the value of ν 's posterior kernel (the exponential of the expression in (33)) at each of the grid nodes and denote the resultant vector by

$$p(\nu) = (p(\nu_1), p(\nu_2), \dots, p(\nu_J)) \tag{34}$$

- Normalize $p(\nu)$ by dividing each vector component in (34) by the quantity $\sum_{j=1}^J p(\nu_j)(\nu_2 - \nu_1)$. For convenience of notation, let us redefine $p(\nu)$ to denote the vector of (normalized) posterior density values at each node of ν 's grid.
- Compute the empirical cumulative distribution function (CDF),

$$F(\nu) = \left(p(\nu_1), \sum_{j=1}^2 p(\nu_j), \dots, \sum_{j=1}^J p(\nu_j) \right) \tag{35}$$

If the grid is adequate, the first element of $F(\nu)$ should be nearly 0, while the last element of $F(\nu)$ nearly 1.

- Draw an observation from the uniform distribution ($U[0, 1]$) and denote it by u .
- Find the element of $F(\nu)$ closest to u without exceeding it.
- The grid node corresponding to the value of $F(\nu)$ in the previous step is the draw of ν from its posterior distribution.

The method above of obtaining a draw from ν 's distribution using its CDF is called the CDF inversion method.

Constructing an adequate grid is the key to efficient sampling from ν 's posterior. Since the gridy Gibbs sampling procedure relies on multiple evaluations of the posterior kernel, two desired characteristics of an adequate grid are short length and coverage of the parameter support where the posterior distribution has positive probability mass. A simple example illustrates this point. Suppose that for a given sample of observed data, the likely values of ν are in the interval (2, 15). Suppose further that we construct an equally-spaced grid of length 30, with nodes on each integer from 2 to 30. The value of the posterior kernel at the nodes corresponding to ν equal to 16 and above would be only marginally different from zero. The posterior kernel evaluations at those nodes should be avoided, if possible.

If no prior intuition exists about what the likely parameter values are, one could employ a variable grid instead of a fixed grid. At each iteration of the sampling algorithm one must analyze the distribution of posterior mass and adjust the grid, so that the majority of the grid nodes are placed in the interval of greatest probability mass. Automating this process could involve some computational effort.

KEY POINTS

- The unconditional density of the return in GARCH models is not available in closed form. Therefore, the likelihood function of the GARCH parameters is expressed as a product of the return's conditional density in each period.
- In the Bayesian setting, estimation of GARCH models is performed numerically.
- Posterior numerical simulations are facilitated if the scale mixture of normal distributions representation is adopted for the Student's t distribution.
- Markov-switching GARCH models provide maximal flexibility in modeling transitions of the volatility dynamics across regimes.

- Transitions among regimes are governed by an unobserved state variable.
- In posterior simulations, the whole path of regimes, governed by the state variable, is simulated together with the model parameters.

NOTES

1. To see that, notice that when F_t is defined as an information set consisting of lagged asset returns, $F_1 = F_0 \cup r_1$, $F_2 = F_1 \cup r_2$, etc.
2. For a discussion of numerical estimation methods, see, for example, Rachev, et al. (2008). See also Geweke (1989) for an application of importance sampling to the estimation of ARCH models.
3. It is possible to assert a prior distribution for ω , α , and β defined on the whole real line, for example, a normal distribution. To respect the positivity constraints on the parameters, such a prior would have to be truncated at the lower bound of the parameters' range. In practice, however, the constraints could also be enforced during the posterior simulation as explained further below. Alternatively, one could assert such a prior without enforcing constraints, after transforming ω , α , and β by taking their logarithms (their ranges then become the whole real line).
4. Many heavy-tailed distributions can be represented as (mean-) scale mixtures of normal distributions. Such representations make estimation based on numerical, iterative procedures easier. See, for example, Fernandez and Steel (2000) for a discussion of the Bayesian treatment of regression analysis with mixtures of normals. In continuous time, the mean and scale mixture of normals models lead to the so-called subordinated processes, widely used in mathematical and empirical finance. Rachev and Mitnik (2000) offer an extensive treatment of subordinated processes.
5. This is an example of the technique known as "data augmentation." It consists of introducing latent (unobserved) variables to help construct efficient simulation algorithms. For a (technical) review of data augmentation, see, for example, van Dyk and Meng (2001).
6. Recall that we assume that $\mu_t = 0$.
7. The Hessian matrix is the matrix of second derivatives. According to a fundamental result in maximum likelihood theory, the maximum likelihood estimator's distribution is asymptotically normal, with covariance matrix—the negative inverse Hessian matrix, evaluated at the maximum likelihood estimate. Usually, the Hessian is provided as a "by-product" of numerical optimization routines for finding the maximum-likelihood estimate. See, for example, Rachev, et al. (2008) for additional details.
8. It is certainly possible to introduce (test for) a deterministic permanent shift in a model parameter into the regime-switching model. For example, Kim and Nelson (1999) apply such a model to a Bayesian investigation of business cycle fluctuations. See also Carlin, Gelfand, and Smith (1992). Wang and Zivot (2000) consider Bayesian estimation of a heteroskedastic model with structural breaks only. The variance in that investigation, however, does not evolve according to an ARCH-type process.
9. See also Haas, Mitnik, and Paoletta (2004), Klaassen (1998), Francq and Zakoian (2001), and Ghysels, McCulloch, and Tsay (1998), among others.
10. The beta distribution is the conjugate distribution for the probability parameter in a binomial experiment.
11. A K -dimensional random variable $\mathbf{p} = (p_1, p_2, \dots, p_K)$, where $p_k \geq 0$ and $\sum_{k=1}^K p_k = 1$, distributed with a Dirichlet distribution with parameters $\mathbf{a} = (a_1, a_2, \dots, a_K)$, $a_i > 0, i = 1, \dots, K$,

has a density function

$$f(\mathbf{p} | \mathbf{a}) = \frac{\Gamma(\sum_{k=1}^K a_k)}{\prod_{k=1}^K \Gamma(a_k)} \prod_{k=1}^K p_k^{a_k-1}$$

where Γ is the gamma function. The mean and the variance of the Dirichlet distribution are given, respectively, by $E(p_k) = \frac{a_k}{a_0}$ and $\text{var}(p_k) = \frac{a_k(a_0 - a_k)}{a_0^2(a_0 + 1)}$, where $a_0 = \sum_{j=1}^K a_j$. The Dirichlet distribution is the conjugate prior distribution for the parameters of the multinomial distribution. As can be seen in our discussion on the MS GARCH (1,1) estimation, the distribution of the Markov chain, $\{S_t\}_{t=1}^T$, is, in fact, a multinomial distribution.

12. See, for example, Anderson (2003).
13. This is the typical range of the degrees-of-freedom parameter of a Student's t distribution fitted to return data. The higher the data frequency is, the more heavy-tailed returns are and the lower the value of the degrees-of-freedom parameter.

Abstract: Investment policies constructed using inferior estimates, such as sample means and sample covariance matrices, typically perform very poorly in practice. Besides introducing spurious changes in portfolio weights each time the portfolio is rebalanced, this undesirable property also results in unnecessary turnover and increased transaction costs. These phenomena are not necessarily a sign that portfolio optimization does not work, but rather that the modern portfolio theory framework is very sensitive to the accuracy of inputs. There are different ways to address this issue. On the estimation side, one can try to produce more *robust estimates* of the input parameters for the optimization problems. This is most often achieved by using estimators that are less sensitive to outliers, and possibly, other sampling errors, such as Bayesian and shrinkage estimators. On the modeling side, one can constrain portfolio weights, use portfolio *resampling*, or apply robust or stochastic optimization techniques to specify scenarios or ranges of values for parameters estimated from data, thus incorporating uncertainty into the optimization process itself.

In this entry, we provide a general overview of some of the common problems encountered in mean-variance optimization before we turn our attention to shrinkage estimators for expected returns and the covariance matrix. Within the context of *Bayesian estimation*, we focus on the Black-Litterman model (see Black and Litterman, 1992). We derive

the model using so-called mixed estimation from classical econometrics. Introducing a simple cross-sectional momentum strategy, we then show how one can combine this strategy with market equilibrium using the Black-Litterman model in the mean-variance framework to rebalance the portfolio on a monthly basis.

PRACTICAL PROBLEMS ENCOUNTERED IN MEAN-VARIANCE OPTIMIZATION

The simplicity and the intuitive appeal of portfolio construction using modern portfolio theory have attracted significant attention both in academia and in practice. Yet, despite considerable effort, it took many years until portfolio managers started using modern portfolio theory for managing real money. Unfortunately, in real world applications there are many problems with it, and portfolio optimization is still considered by many practitioners to be difficult to apply. In this section we consider some of the typical problems encountered in mean-variance optimization. In particular, we elaborate on: (1) the sensitivity to estimation error; (2) the effects of uncertainty in the inputs in the optimization process; and (3) the large data requirement necessary for accurately estimating the inputs for the portfolio optimization framework. We start by considering an example illustrating the effect of estimation error.

Example: The True, Estimated, and Actual Efficient Frontiers

Broadie introduced the terms true frontier, estimated frontier, and actual frontier to refer to the efficient frontiers computed using the true expected returns (unobservable), estimated expected returns, and true expected returns of the portfolios on the estimated frontier, respectively.¹ In this example, we refer to the frontier computed using the true, but unknown, expected returns as the true frontier. Similarly, we refer to the frontier computed using estimates of the expected returns and the true covariance matrix as the estimated frontier. Finally, we define the actual frontier as follows: We take the portfolios on the estimated frontier and then calculate their expected returns using the true expected returns. Since we are using the true covariance matrix, the variance of a port-

folio on the estimated frontier is the same as the variance on the actual frontier.

From these definitions, we observe that the actual frontier will always lie below the true frontier. The estimated frontier can lie anywhere with respect to the other frontiers. However, if the errors in the expected return estimates have a mean of zero, then the estimated frontier will lie above the true frontier with extremely high probability, particularly when the investment universe is large. We look at two cases considered by Ceria and Stubbs:²

1. Using the covariance matrix and expected return vector from Idzorek (2005), they randomly generate a time series of normally distributed returns and compute the average to use as estimates of expected returns. Using the expected-return estimate calculated in this fashion and the true covariance matrix, they generate an estimated efficient frontier of risk versus expected return where the portfolios were subject to no-shorting constraints and the standard budget constraint that the sum of portfolio weights is one. Similarly, Ceria and Stubbs compute the true efficient frontier using the original covariance matrix and expected return vector. Finally, they construct the actual frontier by computing the expected return and risk of the portfolios on the estimated frontier with the true covariance and expected return values. These three frontiers are illustrated in Figure 1.
2. Using the same estimate of expected returns, Ceria and Stubbs also generate risk versus expected return where active holdings of the assets are constrained to be $\pm 3\%$ of the benchmark holding of each asset. These frontiers are illustrated in Figure 2.

We observe that the estimated frontiers significantly overestimate the expected return for any risk level in both types of frontiers. More importantly, we note that the actual frontier lies far below the true frontier in both cases. This shows that the optimal mean-variance

portfolio is not necessarily a good portfolio; that is, it is not mean-variance efficient. Since the true expected return is not observable, we do not know how far the actual expected return may be from the expected return of the mean-variance optimal portfolio, and we end up holding an inferior portfolio.

Sensitivity to Estimation Error

In a portfolio optimization context, securities with large expected returns and low standard deviations will be overweighted and conversely, securities with low expected re-

turns and high standard deviations will be underweighted. Therefore, large estimation errors in expected returns and/or variances/covariances introduce errors in the optimized portfolio weights. For this reason, people often cynically refer to optimizers as error maximizers.

Uncertainty from estimation error in expected returns tends to have more influence than in the covariance matrix in a mean-variance optimization.³ The relative importance depends on the investor’s risk aversion, but as a general rule of thumb, errors in the expected returns are about 10 times more important than errors in the covariance matrix, and errors in the variances are about twice as important as errors in the covariances.⁴ As the risk tolerance increases, the relative impact of estimation errors in the expected returns becomes even more important. Conversely, as the risk tolerance decreases, the impact of errors in expected returns relative to errors in the covariance matrix becomes smaller. From this simple rule, it follows that the major focus should be on providing good estimates for the expected returns, followed by the variances. In this entry we discuss shrinkage techniques and the *Black-Litterman model* in order to mitigate estimation errors.

Constraining Portfolio Weights

Several studies have shown that the inclusion of constraints in the mean-variance optimization problem leads to better out-of-sample performance.⁵ Practitioners often use no short-selling constraints or upper and lower bounds for each security to avoid overconcentration in a few assets. Gupta and Eichhorn (1998) suggest that constraining portfolio weights may also assist in containing volatility, increase realized efficiency, and decrease downside risk or shortfall probability.

Jagannathan and Ma (2003) provide a theoretical justification for these observations. Specifically, they show that the no short-selling constraints are equivalent to reducing the

 Reprinted with the permission of Axioma, Inc.

estimated asset covariances, whereas upper bounds are equivalent to increasing the corresponding covariances. For example, stocks that have high covariance with other stocks tend to receive negative portfolio weights. Therefore, when their covariance is decreased (which is equivalent to the effect of imposing no short-selling constraints), these negative weights disappear. Similarly, stocks that have low covariances with other stocks tend to get overweighted. Hence, by increasing the corresponding covariances the impact of these overweighted stocks decreases.

Furthermore, Monte Carlo experiments performed by Jagannathan and Ma indicate that when no-short-sell constraints are imposed, the sample covariance matrix has about the same performance (as measured by the global minimum variance (GMV) portfolio) as a covariance matrix estimator constructed from a factor structure.

Care needs to be taken when imposing constraints for robustness and stability purposes. For example, if the constraints used are too tight, they will completely determine the portfolio allocation—not the forecasts.

Instead of providing ad hoc upper and lower bounds on each security, as proposed by Bouchaud, Potters, and Aguilar (1997), one can use so-called diversification indicators that measure the concentration of the portfolio. These diversification indicators can be used as constraints in the portfolio construction phase to limit the concentration to individual securities. The authors demonstrate that these indicators are related to the information content of the portfolio in the sense of information theory.⁶ For example, a very concentrated portfolio corresponds to a large information content (as we would only choose a very concentrated allocation if our information about future price fluctuations is perfect), whereas an equally weighted portfolio would indicate low information content (as we would not put “all the eggs in one basket” if our information about future price fluctuations is poor).

Importance of Sensitivity Analysis

In practice, in order to minimize dramatic changes due to estimation error, it is advisable to perform sensitivity analysis. For example, one can study the results of small changes or perturbations to the inputs from an efficient portfolio selected from a mean-variance optimization. If the portfolio calculated from the perturbed inputs drastically differs from the first one, this might indicate a problem. The perturbation can also be performed on a security by security basis in order to identify those securities that are the most sensitive. The objective of this sensitivity analysis is to identify a set of security weights that will be close to efficient under several different sets of plausible inputs.

Issues with Highly Correlated Assets

The inclusion of highly correlated securities is another major cause for instability in the *mean-variance optimization* framework. For example, high correlation coefficients among common asset classes are one reason why real estate is popular in optimized portfolios. Real estate is one of the few asset classes that has a low correlation with other common asset classes. But real estate in general does not have the liquidity necessary in order to implement these portfolios and may therefore fail to deliver the return promised by the real estate indexes.

The problem of high correlations typically becomes worse when the correlation matrix is estimated from historical data. Specifically, when the correlation matrix is estimated over a slightly different period, correlations may change, but the impact on the new portfolio weights may be drastic. In these situations, it may be a good idea to resort to a *shrinkage estimator* or a factor model to model covariances and correlations.

Incorporating Uncertainty in the Inputs into the Portfolio Allocation Process

In the classical mean-variance optimization problem, the expected returns and the

covariance matrix of returns are uncertain and have to be estimated. After the estimation of these quantities, the portfolio optimization problem is solved as a deterministic problem—completely ignoring the uncertainty in the inputs. However, it makes sense for the uncertainty of expected returns and risk to enter into the optimization process, thus creating a more realistic model. Using point estimates of the expected returns and the covariance matrix of returns, and treating them as error-free in portfolio allocation does not necessarily correspond to prudent investor behavior.

The investor would probably be more comfortable choosing a portfolio that would perform well under a number of different scenarios, thereby also attaining some protection from estimation risk and model risk. Obviously, to have some insurance in the event of less likely but more extreme cases (e.g., scenarios that are highly unlikely under the assumption that returns are normally distributed), the investor must be willing to give up some of the upside that would result under the more likely scenarios. Such an investor seeks a robust portfolio, that is, a portfolio that is assured against some worst-case model misspecification. The estimation process can be improved through robust statistical techniques such as shrinkage and Bayesian estimators discussed later in this entry. However, jointly considering estimation risk and model risk in the financial decision-making process is becoming more important.

The estimation process frequently does not deliver a point forecast (that is, one single number), but a full distribution of expected returns. Recent approaches attempt to integrate estimation risk into the mean-variance framework by using the expected return distribution in the optimization. A simple approach is to sample from the return distribution and average the resulting portfolios (Monte Carlo approach).⁷ However, as a mean-variance problem has to be solved for each draw, this is computationally intensive for larger portfolios. In addition, the

averaging does not guarantee that the resulting portfolio weights will satisfy all constraints.

Introduced in the late 1990s by Ben-Tal and Nemirovski (1998, 1999) and El Ghaoui and Lebret (1997) the *robust optimization* framework is computationally more efficient than the Monte Carlo approach. This development in optimization technology allows for efficiently solving the robust version of the mean-variance optimization problem in about the same time as the classical mean-variance optimization problem. The technique explicitly uses the distribution from the estimation process to find a robust portfolio in one single optimization. It thereby incorporates uncertainties of inputs into a deterministic framework. The classical portfolio optimization formulations such as the mean-variance portfolio selection problem, the maximum Sharpe ratio portfolio problem, and the value-at-risk (VaR) portfolio problem all have robust counterparts that can be solved in roughly the same amount of time as the original problem.⁸

Large Data Requirements

In classical mean-variance optimization, we need to provide estimates of the expected returns and covariances of all the securities in the investment universe considered. Typically, however, portfolio managers have reliable return forecasts for only a small subset of these assets. This is probably one of the major reasons why the mean-variance framework has not been adopted by practitioners in general. It is simply unreasonable for the portfolio manager to produce good estimates of all the inputs required in classical portfolio theory.

We will see later in this entry that the Black-Litterman model provides a remedy in that it blends any views (this could be a forecast on just one or a few securities, or all of them) the investor might have with the market equilibrium. When no views are present, the resulting Black-Litterman expected returns are

just the expected returns consistent with the market equilibrium. Conversely, when the investor has views on some of the assets, the resulting expected returns deviate from market equilibrium.

SHRINKAGE ESTIMATION

It is well known since the seminal work by Stein (1956) that biased estimators often yield better parameter estimates than their generally preferred unbiased counterparts. In particular, it can be shown that if we consider the problem of estimating the mean of an N -dimensional multivariate normal variable ($N > 2$), $X \in N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ with known covariance matrix $\boldsymbol{\Sigma}$, the sample mean $\hat{\boldsymbol{\mu}}$ is not the best estimator of the population mean $\boldsymbol{\mu}$ in terms of the quadratic loss function

$$L(\boldsymbol{\mu}, \hat{\boldsymbol{\mu}}) = (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}})' \boldsymbol{\Sigma}^{-1} (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}})$$

For example, the so-called James-Stein shrinkage estimator

$$\hat{\boldsymbol{\mu}}_{JS} = (1 - w)\hat{\boldsymbol{\mu}} + w\boldsymbol{\mu}_0\boldsymbol{\iota}$$

has a lower quadratic loss than the sample mean, where

$$w = \min\left(1, \frac{N - 2}{T(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0\boldsymbol{\iota})' \boldsymbol{\Sigma}^{-1} (\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0\boldsymbol{\iota})}\right)$$

and $\boldsymbol{\iota} = [1, 1, \dots, 1]'$. Moreover, T is the number of observations, and $\boldsymbol{\mu}_0$ is an arbitrary number. The vector $\boldsymbol{\mu}_0\boldsymbol{\iota}$ and the weight w are referred to as the shrinkage target and the shrinkage intensity (or shrinkage factor), respectively. Although there are some choices of $\boldsymbol{\mu}_0$ that are better than others, what is surprising with this result is that it could be any number! This fact is referred to as the Stein paradox.

In effect, shrinkage is a form of averaging different estimators. The shrinkage estimator typically consists of three components: (1) an estimator with little or no structure (like the sample mean above); (2) an estimator with a lot of structure (the shrinkage target); and (3) the shrinkage intensity. The shrinkage target is

chosen with the following two requirements in mind. First, it should have only a small number of free parameters (robust and with a lot of structure). Second, it should have some of the basic properties in common with the unknown quantity being estimated. The shrinkage intensity can be chosen based on theoretical properties or simply by numerical simulation.

Probably the most well-known shrinkage estimator⁹ used to estimate expected returns in the financial literature is the one proposed by Jorion (1986) where the shrinkage target is given by $\boldsymbol{\mu}_g\boldsymbol{\iota}$ with

$$\boldsymbol{\mu}_g = \frac{\boldsymbol{\iota}' \boldsymbol{\Sigma}^{-1} \hat{\boldsymbol{\mu}}}{\boldsymbol{\iota}' \boldsymbol{\Sigma}^{-1} \boldsymbol{\iota}}$$

and

$$w = \frac{N + 2}{N + 2 + T(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_g\boldsymbol{\iota})' \boldsymbol{\Sigma}^{-1} (\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_g\boldsymbol{\iota})}$$

We note that $\boldsymbol{\mu}_g$ is the return on the GMV portfolio. Several studies document that for the mean-variance framework: (1) the variability in the portfolio weights from one period to the next decrease; and (2) the out-of-sample risk-adjusted performance improves significantly when using a shrinkage estimator as compared to the sample mean.¹⁰

We can also apply the shrinkage technique for covariance matrix estimation. This involves shrinking an unstructured covariance estimator toward a more structured covariance estimator. Typically the structured covariance estimator only has a few degrees of freedom (only a few nonzero eigenvalues) as motivated by random matrix theory.

For example, as shrinkage targets, Ledoit and Wolf (2003, 2004) suggest using the covariance matrix that follows from the single-factor model developed by Sharpe (1963) or the constant correlation covariance matrix.¹¹ In practice the single-factor model and the constant correlation model yield similar results, but the constant correlation model is much easier to implement. In the case of the constant correlation model, the shrinkage estimator for the covariance matrix

takes the form

$$\hat{\Sigma}_{LW} = w\hat{\Sigma}_{CC} + (1 - w)\hat{\Sigma}$$

where $\hat{\Sigma}$ is the sample covariance matrix, and $\hat{\Sigma}_{CC}$ is the sample covariance matrix with constant correlation. The sample covariance matrix with constant correlation is computed as follows.

First, we decompose the sample covariance matrix according to

$$\hat{\Sigma} = \Lambda C \Lambda'$$

where Λ is a diagonal matrix of the volatilities of returns and C is the sample correlation matrix, that is,

$$C = \begin{bmatrix} 1 & \hat{\rho}_{12} & \cdots & \hat{\rho}_{1N} \\ \hat{\rho}_{21} & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \hat{\rho}_{N-1N} \\ \hat{\rho}_{N1} & \cdots & \hat{\rho}_{NN-1} & 1 \end{bmatrix}$$

Second, we replace the sample correlation matrix with the constant correlation matrix

$$C_{CC} = \begin{bmatrix} 1 & \hat{\rho} & \cdots & \hat{\rho} \\ \hat{\rho} & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \hat{\rho} \\ \hat{\rho} & \cdots & \hat{\rho} & 1 \end{bmatrix}$$

where $\hat{\rho}$ is the average of all the sample correlations, in other words

$$\hat{\rho} = \frac{2}{(N-1)N} \sum_{i=1}^N \sum_{j=i+1}^N \hat{\rho}_{ij}$$

The optimal shrinkage intensity can be shown to be proportional to a constant divided by the length of the history, T .¹²

Ledoit and Wolf (2003, 2004) compare the empirical out-of-sample performance of their shrinkage covariance matrix estimators with other covariance matrix estimators, such as the sample covariance matrix, a statistical factor model based on the first five principal components, and a factor model based on the 48 industry factors as defined by Fama and French (1997). The results indicate that when it comes

to computing a GMV portfolio, their shrinkage estimators are superior compared to the others tested, with the constant correlation shrinkage estimator coming out slightly ahead. Interestingly enough, it turns out that the shrinkage intensity for the single-factor model (the shrinkage intensity for the constant coefficient model is not reported) is fairly constant throughout time with a value around 0.8. This suggests that there is about four times as much estimation error present in the sample covariance matrix as there is bias in the single-factor covariance matrix.

THE BLACK-LITTERMAN MODEL

In the Black-Litterman model an estimate of future expected returns is based on combining market equilibrium (e.g., the CAPM equilibrium) with an investor's views. As we will see, the Black-Litterman expected return is a shrinkage estimator where market equilibrium is the shrinkage target and the shrinkage intensity is determined by the portfolio manager's confidence in the model inputs. We will make this statement precise later in this section. Such views are expressed as absolute or relative deviations from equilibrium together with confidence levels of the views (as measured by the standard deviation of the views).

The Black-Litterman expected return is calculated as a weighted average of the market equilibrium and the investor's views. The weights depend on (1) the volatility of each asset and its correlations with the other assets and (2) the degree of confidence in each forecast. The resulting expected return, which is the mean of the posterior distribution, is then used as input in the portfolio optimization process. Portfolio weights computed in this fashion tend to be more intuitive and less sensitive to small changes in the original inputs (i.e., forecasts of market equilibrium, investor's views, and the covariance matrix).

The Black-Litterman model can be interpreted as a Bayesian model. Named after the English mathematician Thomas Bayes, the Bayesian approach is based on the subjective interpretation of probability. A probability distribution is used to represent an investor's belief on the probability that a specific event will actually occur. This probability distribution, called the prior distribution, reflects an investor's knowledge about the probability before any data are observed. After more information is provided (e.g., data observed), the investor's opinions about the probability might change. Bayes' rule is the formula for computing the new probability distribution, called the posterior distribution. The posterior distribution is based on knowledge of the prior probability distribution plus the new data. A posterior distribution of expected return is derived by combining the forecast from the empirical data with a prior distribution.

The ability to incorporate exogenous insight, such as a portfolio manager's judgment, into formal models is important: Such insight might be the most valuable input used by the model. The Bayesian framework allows forecasting systems to use such external information sources and subjective interventions (i.e., modification of the model due to judgment) in addition to traditional information sources such as market data and proprietary data.

Because portfolio managers might not be willing to give up control to a black box, incorporating exogenous insights into formal models through Bayesian techniques is one way of giving the portfolio manager better control in a quantitative framework. Forecasts are represented through probability distributions that can be modified or adjusted to incorporate other sources of information deemed relevant. The only restriction is that such additional information (i.e., the investor's views) be combined with the existing model through the laws of probability. In effect, incorporating Bayesian views into a model allows one to rationalize subjectivity within a formal, quanti-

tative framework. "[T]he rational investor is a Bayesian," as Markowitz noted (1987, p. 57).

Derivation of the Black-Litterman Model

The basic feature of the Black-Litterman model that we discuss in this and the following sections is that it combines an investor's views with the market equilibrium. Let us understand what this statement implies. In the classical mean-variance optimization framework an investor is required to provide estimates of the expected returns and covariances of all the securities in the investment universe considered. This is of course a humongous task, given the number of securities available today. Portfolio and investment managers are very unlikely to have a detailed understanding of all the securities, companies, industries, and sectors that they have at their disposal. Typically, most of them have a specific area of expertise that they focus on in order to achieve superior returns.

This is probably one of the major reasons why the mean-variance framework has not been adopted among practitioners in general. It is simply unrealistic for the portfolio manager to produce reasonable estimates (besides the additional problems of estimation error) of the inputs required in classical portfolio theory.

Furthermore, many trading strategies used today cannot easily be turned into forecasts of expected returns and covariances. In particular, not all trading strategies produce views on absolute return, but rather just provide relative rankings of securities that are predicted to outperform/underperform other securities. For example, considering two stocks, A and B, instead of the absolute view, "the one-month expected return on A and B are 1.2% and 1.7% with a standard deviation of 5% and 5.5%, respectively," a relative view may be of the form "B will outperform A with half a percent over the next month" or simply "B will outperform

A over the next month.” Clearly, it is not an easy task to translate any of these relative views into the inputs required for the modern portfolio theoretical framework. We now walk through and illustrate the usage of the Black-Litterman model in three simple steps.

Step 1: Basic Assumptions and Starting Point

One of the basic assumptions underlying the Black-Litterman model is that the expected return of a security should be consistent with market equilibrium unless the investor has a specific view on the security. In other words, an investor who does not have any views on the market should hold the market.¹³

Our starting point is the CAPM model:

$$E(R_i) - R_f = \beta_i(E(R_M) - R_f)$$

where $E(R_i)$, $E(R_M)$, and R_f are the expected return on security i , the expected return on the market portfolio, and the risk-free rate, respectively. Furthermore,

$$\beta_i = \frac{\text{cov}(R_i, R_M)}{\sigma_M^2}$$

where σ_M^2 is the variance of the market portfolio. Let us denote by $\mathbf{w}_b = (w_{b1}, \dots, w_{bN})'$ the market capitalization or benchmark weights, so that with an asset universe of N securities¹⁴ the return on the market can be written as

$$R_M = \sum_{j=1}^N w_{bj} R_j$$

Then by the CAPM, the expected excess return on asset i , $\Pi_i = E(R_i) - R_f$, becomes

$$\begin{aligned} \Pi_i &= \beta_i(E(R_M) - R_f) \\ &= \frac{\text{cov}(R_i, R_M)}{\sigma_M^2}(E(R_M) - R_f) \\ &= \frac{E(R_M) - R_f}{\sigma_M^2} \sum_{j=1}^N \text{cov}(R_i, R_j) w_{bj} \end{aligned}$$

We can also express this in matrix-vector form as

$$\mathbf{\Pi} = \delta \mathbf{\Sigma} \mathbf{w}$$

where we define the market price of risk as

$$\delta = \frac{E(R_M) - R_f}{\sigma_M^2}$$

the expected excess return vector

$$\mathbf{\Pi} = \begin{bmatrix} \Pi_1 \\ \vdots \\ \Pi_N \end{bmatrix}$$

and the covariance matrix of returns

$$\mathbf{\Sigma} = \begin{bmatrix} \text{cov}(R_1, R_1) & \cdots & \text{cov}(R_1, R_N) \\ \vdots & \ddots & \vdots \\ \text{cov}(R_N, R_1) & \cdots & \text{cov}(R_N, R_N) \end{bmatrix}$$

The true expected returns $\boldsymbol{\mu}$ of the securities are unknown. However, we assume that our previous equilibrium model serves as a reasonable estimate of the true expected returns in the sense that

$$\mathbf{\Pi} = \boldsymbol{\mu} + \boldsymbol{\varepsilon}_\Pi, \boldsymbol{\varepsilon}_\Pi \sim N(0, \tau \mathbf{\Sigma})$$

for some small parameter $\tau \ll 1$. We can think about $\tau \mathbf{\Sigma}$ as our confidence in how well we can estimate the equilibrium of expected returns. In other words, a small τ implies a high confidence in our equilibrium estimates and vice versa.

According to portfolio theory, because the market portfolio is on the efficient frontier, as a consequence of the CAPM an investor will be holding a portfolio consisting of the market portfolio and a risk-free instrument earning the risk-free rate. But let us now see what happens if an investor has a particular view on some of the securities.

Step 2: Expressing an Investor's Views

Formally, K views in the Black-Litterman model are expressed as a K -dimensional vector \mathbf{q} with

$$\mathbf{q} = \mathbf{P} \boldsymbol{\mu} + \boldsymbol{\varepsilon}_q, \boldsymbol{\varepsilon}_q \sim N(0, \boldsymbol{\Omega})$$

where \mathbf{P} is a $K \times N$ matrix (explained in the following example) and $\boldsymbol{\Omega}$ is a $K \times K$ matrix expressing the confidence in the views. In order to understand this mathematical specification better, let us take a look at an example.

Let us assume that the asset universe that we consider has five stocks ($N = 5$) and that an investor has the following two views:

1. Stock 1 will have a return of 1.5%.
2. Stock 3 will outperform Stock 2 by 4%.

We recognize that the first view is an absolute view whereas the second one is a relative view. Mathematically, we express the two views together as

$$\begin{bmatrix} 1.5\% \\ 4\% \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \\ \mu_5 \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \end{bmatrix}$$

The first row of the \mathbf{P} matrix represents the first view, and similarly, the second row describes the second view. In this example, we chose the weights of the second view such that they add up to zero, but other weighting schemes are also possible. For instance, the weights could also be chosen as some scaling factor times one over the market capitalizations of the stock, some scaling factor times one over the stock price, or other variations thereof. We come back to these issues later in this section when we discuss how to incorporate time-series-based strategies and cross-sectional ranking strategies.

We also remark at this point that the error terms ε_1 , ε_2 do not explicitly enter into the Black-Litterman model—but their variances do. Quite simply, these are just the variances of the different views. Although in some instances they are directly available as a by-product of the view or the strategy, in other cases they need to be estimated separately. For example,

$$\mathbf{\Omega} = \begin{bmatrix} 1\%^2 & 0 \\ 0 & 1\%^2 \end{bmatrix}$$

corresponds to a higher confidence in the views, and conversely,

$$\mathbf{\Omega} = \begin{bmatrix} 5\%^2 & 0 \\ 0 & 7\%^2 \end{bmatrix}$$

represents a much lower confidence in the views. We discuss a few different approaches in choosing the confidence levels below. The off-diagonal elements of $\mathbf{\Omega}$ are typically set to zero. The reason for this is that the error terms of the individual views are most often assumed to be independent of one another.

Step 3: Combining an Investor's Views with Market Equilibrium

Having specified the market equilibrium and an investor's views separately, we are now ready to combine the two. There are two different, but equivalent, approaches that can be used to arrive at the Black-Litterman model. We will describe a derivation that relies upon standard econometrical techniques, in particular, the so-called mixed estimation technique described by Theil (1971). The approach based on Bayesian statistics has been explained in some detail by Satchell and Scowcroft (2000).

Let us first recall the specification of market equilibrium

$$\mathbf{\Pi} = \boldsymbol{\mu} + \boldsymbol{\varepsilon}_{\Pi}, \boldsymbol{\varepsilon}_{\Pi} \sim N(0, \tau \boldsymbol{\Sigma})$$

and the one for the investor's views

$$\mathbf{q} = \mathbf{P}\boldsymbol{\mu} + \boldsymbol{\varepsilon}_{\mathbf{q}}, \boldsymbol{\varepsilon}_{\mathbf{q}} \sim N(0, \boldsymbol{\Omega})$$

We can stack these two equations together in the form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\mu} + \boldsymbol{\varepsilon}, \boldsymbol{\varepsilon} \sim N(0, \mathbf{V})$$

where

$$\mathbf{y} = \begin{bmatrix} \mathbf{\Pi} \\ \mathbf{q} \end{bmatrix}, \mathbf{X} = \begin{bmatrix} \mathbf{I} \\ \mathbf{P} \end{bmatrix}, \mathbf{V} = \begin{bmatrix} \tau \boldsymbol{\Sigma} & \\ & \boldsymbol{\Omega} \end{bmatrix}$$

with \mathbf{I} denoting the $N \times N$ identity matrix. We observe that this is just a standard linear model for the expected returns $\boldsymbol{\mu}$. Calculating the generalized least squares (GLS) estimator for $\boldsymbol{\mu}$, we

obtain

$$\begin{aligned}
 \hat{\boldsymbol{\mu}}_{BL} &= (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y} \\
 &= \left(\begin{bmatrix} \mathbf{I} & \mathbf{P}' \end{bmatrix} \begin{bmatrix} (\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} & \\ & \boldsymbol{\Omega}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} \\ \boldsymbol{\Pi} \end{bmatrix} \right)^{-1} \\
 &\quad \times \begin{bmatrix} \mathbf{I} & \mathbf{P}' \end{bmatrix} \begin{bmatrix} (\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} & \\ & \boldsymbol{\Omega}^{-1} \end{bmatrix} \begin{bmatrix} \boldsymbol{\Pi} \\ \mathbf{q} \end{bmatrix} \\
 &= \left(\begin{bmatrix} \mathbf{I} & \mathbf{P}' \end{bmatrix} \begin{bmatrix} (\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} \\ \boldsymbol{\Omega}^{-1}\mathbf{P}' \end{bmatrix} \right)^{-1} \begin{bmatrix} \mathbf{I} & \mathbf{P}' \end{bmatrix} \begin{bmatrix} (\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1}\boldsymbol{\Pi} \\ \boldsymbol{\Omega}^{-1}\mathbf{q} \end{bmatrix} \\
 &= [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}']^{-1} [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1}\boldsymbol{\Pi} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{q}]
 \end{aligned}$$

The last line in the above formula is the Black-Litterman expected returns that blend the market equilibrium with the investor's views.

Some Remarks and Observations

Following are some comments in order to provide a better intuitive understanding of the formula. We see that if the investor has no views (that is, $\mathbf{q} = \boldsymbol{\Omega} = 0$) or the confidence in the views is zero, then the Black-Litterman expected return becomes $\hat{\boldsymbol{\mu}}_{BL} = \boldsymbol{\Pi}$. Consequently, the investor will end up holding the market portfolio as predicted by the CAPM. In other words, the optimal portfolio in the absence of views is the defined market.

If we were to plug return targets of zero or use the available cash rates, for example, into an optimizer to represent the absence of views, the result would be an optimal portfolio that looks very much different from the market. The equilibrium returns are those forecasts that in the absence of any other views will produce an optimal portfolio equal to the market portfolio. Intuitively speaking, the equilibrium returns in the Black-Litterman model are used to center the optimal portfolio around the market portfolio.

By using $\mathbf{q} = \mathbf{P}\boldsymbol{\mu} + \boldsymbol{\varepsilon}_q$, we have that the investor's views alone imply the estimate of expected returns $\hat{\boldsymbol{\mu}} = (\mathbf{P}'\mathbf{P})^{-1}\mathbf{P}'\mathbf{q}$. Since $\mathbf{P}(\mathbf{P}'\mathbf{P})^{-1}\mathbf{P}' = \mathbf{I}$ where \mathbf{I} is the identity matrix, we can rewrite the Black-Litterman expected returns in the form

$$\hat{\boldsymbol{\mu}}_{BL} = [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}']^{-1} [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1}\boldsymbol{\Pi} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}\hat{\boldsymbol{\mu}}]$$

Now we see that the Black-Litterman expected return is a confidence weighted linear combination of market equilibrium $\boldsymbol{\Pi}$ and the expected return $\hat{\boldsymbol{\mu}}$ implied by the investor's views. The two weighting matrices are given by

$$\begin{aligned}
 \mathbf{w}_{\boldsymbol{\Pi}} &= [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}']^{-1} (\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} \\
 \mathbf{w}_{\mathbf{q}} &= [(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}']^{-1} \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}
 \end{aligned}$$

where

$$\mathbf{w}_{\boldsymbol{\Pi}} = \mathbf{w}_{\mathbf{q}} = \mathbf{I}$$

In particular, $(\boldsymbol{\tau}\boldsymbol{\Sigma})^{-1}$ and $\mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}$ represent the confidence we have in our estimates of the market equilibrium and the views, respectively. Therefore, if we have low confidence in the views, the resulting expected returns will be close to the ones implied by market equilibrium. Conversely, with higher confidence in the views, the resulting expected returns will deviate from the market equilibrium implied expected returns. We say that we tilt away from market equilibrium.

It is straightforward to show that the Black-Litterman expected returns can also be written in the form

$$\hat{\boldsymbol{\mu}}_{BL} = \boldsymbol{\Pi} + \boldsymbol{\tau}\boldsymbol{\Sigma}\mathbf{P}'(\boldsymbol{\Omega} + \boldsymbol{\tau}\mathbf{P}\boldsymbol{\Sigma}\mathbf{P}')^{-1}(\mathbf{q} - \mathbf{P}\boldsymbol{\Pi})$$

where we now immediately see that we tilt away from the equilibrium with a vector proportional to $\boldsymbol{\Sigma}\mathbf{P}'(\boldsymbol{\Omega} + \boldsymbol{\tau}\mathbf{P}\boldsymbol{\Sigma}\mathbf{P}')^{-1}(\mathbf{q} - \mathbf{P}\boldsymbol{\Pi})$.

We also mention that the Black-Litterman model can be derived as a solution to the following optimization problem:

$$\begin{aligned}
 \hat{\boldsymbol{\mu}}_{BL} &= \arg \min_{\boldsymbol{\mu}} \{ (\boldsymbol{\Pi} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\boldsymbol{\Pi} - \boldsymbol{\mu}) \\
 &\quad + \boldsymbol{\tau}(\mathbf{q} - \mathbf{P}\boldsymbol{\mu})' \boldsymbol{\Omega}^{-1} (\mathbf{q} - \mathbf{P}\boldsymbol{\mu}) \}
 \end{aligned}$$

From this formulation we see that $\hat{\boldsymbol{\mu}}_{BL}$ is chosen such that it is simultaneously as close to $\boldsymbol{\Pi}$, and $\mathbf{P}\boldsymbol{\mu}$ is as close to \mathbf{q} as possible. The distances are determined by $\boldsymbol{\Sigma}^{-1}$ and $\boldsymbol{\Omega}^{-1}$. Furthermore, the relative importance of the equilibrium versus the views is determined by $\boldsymbol{\tau}$. For example, for $\boldsymbol{\tau}$ large the weight of the views is increased,

whereas for τ small the weight of the equilibrium is higher. Moreover, we also see that τ is a redundant parameter as it can be absorbed into Ω .

It is straightforward to calculate the variance of the Black-Litterman combined estimator of the expected returns by the standard sandwich formula, that is,

$$\begin{aligned}\text{var}(\hat{\boldsymbol{\mu}}_{BL}) &= (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1} \\ &= [(\tau\boldsymbol{\Sigma})^{-1} + \mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{P}]^{-1}\end{aligned}$$

The most important feature of the Black-Litterman model is that it uses the mixed estimation procedure to adjust the entire market equilibrium implied expected return vector with an investor's views. Because security returns are correlated, views on just a few assets will, due to these correlations, imply changes to the expected returns on all assets. Mathematically speaking, this follows from the fact that although the vector \mathbf{q} can have dimension $K \ll N$, $\mathbf{P}'\boldsymbol{\Omega}^{-1}$ is an $N \times K$ matrix that propagates the K views into N components, $\mathbf{P}'\boldsymbol{\Omega}^{-1}\mathbf{q}$. This effect is stronger the more correlated the different securities are. In the absence of this adjustment of the expected return vector, the differences between the equilibrium expected return and an investor's forecasts will be interpreted as an arbitrage opportunity by a mean-variance optimizer and result in portfolios concentrated in just a few assets ("corner solutions"). Intuitively, any estimation errors are spread out over all assets, making the Black-Litterman expected return vector less sensitive to errors in individual views. This effect contributes to the mitigation of estimation risk and error maximization in the optimization process.

Practical Considerations and Extensions

In this subsection we discuss a few practical issues in using the Black-Litterman model. Specifically, we discuss how to incorporate factor models and cross-sectional rankings in this framework. Furthermore, we also provide some ideas on how the confidences in the views can

be estimated in cases where these are not directly available.

It is straightforward to incorporate factor models in the Black-Litterman framework. Let us assume we have a factor representation of the returns of some of the assets, that is

$$R_i = \alpha_i + \mathbf{F}\boldsymbol{\beta}_i + \varepsilon_i, i \in I$$

where $I \subset \{1, 2, \dots, N\}$. Typically, from a factor model it is easy to obtain an estimate of the residual variance, $\text{var}(\varepsilon_i)$. In this case, we set

$$q_i = \begin{cases} \alpha_i + \mathbf{F}\boldsymbol{\beta}_i, & i \in I \\ 0, & \text{otherwise} \end{cases}$$

and the corresponding confidence

$$\omega_{ii}^2 = \begin{cases} \text{var}(\varepsilon_i), & i \in I \\ 0, & \text{otherwise} \end{cases}$$

The \mathbf{P} matrix is defined by

$$\begin{aligned}p_{ii} &= \begin{cases} 1, & i \in I \\ 0, & \text{otherwise} \end{cases} \\ p_{ij} &= 0, i \neq j\end{aligned}$$

Of course in a practical implementation we would omit rows with zeros.

Many quantitative investment strategies do not a priori produce expected returns, but rather just a simple ranking of the securities. Let us consider a ranking of securities from best to worst (from an outperforming to an underperforming perspective, etc.). For example, a value manager might consider ranking securities in terms of increasing book-to-price ratio (B/P), where a low B/P would indicate an undervalued stock (potential to increase in value) and high B/P an overvalued stock (potential to decrease in value). From this ranking we form a long-short portfolio where we purchase the top half of the stocks (the group that is expected to outperform) and we sell short the second half of stocks (the group that is expected to underperform). The view \mathbf{q} in this case becomes a scalar, equal to the expected return on the long-short portfolio. The confidence of the view can be decided from backtests, as we describe next. Further, here the \mathbf{P} matrix is a $1 \times N$ matrix of

ones and minus ones. The corresponding column component is set to one if the security belongs to the outperforming group, or minus one if it belongs to the underperforming group.

In many cases we may not have a direct estimate of the expected return and confidence (variance) of the view. There are several different ways to determine the confidence level.

One of the advantages of a quantitative strategy is that it can be backtested. In the case of the long-short portfolio strategy discussed previously, we could estimate its historical variance through simulation with historical data. Of course, we cannot completely judge the performance of a strategy going forward from our backtests. Nevertheless, the backtest methodology allows us to obtain an estimate of the Black-Litterman view and confidence for a particular view/strategy.

Another approach of deriving estimates of the confidence of the view is through simple statistical assumptions. To illustrate, let us consider the second view in the preceding example: "Stock 3 will outperform Stock 2 by 4%." If we don't know its confidence, we can come up with an estimate for it from the answers to a few simple questions. We start asking ourselves with what certainty we believe the strategy will deliver a return between 3% and 5% ($4\% \pm \alpha$ where α is some constant, in this case $\alpha = 1\%$). Let us say that we believe there is a chance of two out of three that this will happen, $2/3 \approx 67\%$. If we assume normality, we can interpret this as a 67% confidence interval for the future return to be in the interval [3%, 5%]. From this confidence interval we calculate that the implied standard deviation is equal to about 0.66%. Therefore, we would set the Black-Litterman confidence equal to $(0.66\%)^2 = 0.43\%$.

Some extensions to the Black-Litterman model have been derived. For example, Satchel and Scowcroft (2000) propose a model where an investor's view on global volatility is incorporated in the prior views by assuming that τ is unknown and stochastic. Idzorek (2005) introduces a new idea for determining the

confidence level of a view. He proposes that the investor derives his confidence level indirectly by first specifying his confidence in the tilt away from equilibrium (the difference between the market capitalization weights and the weights implied by the view alone). Qian and Gorman (2001) describe a technique based on conditional distribution theory that allows an investor to incorporate his views on any or all variances.

Of course other asset classes beyond equities and bonds can be incorporated into the Black-Litterman framework.¹⁵ Some practical experiences and implementation details have been described by Bevan and Winkelmann (1998) and He and Litterman (1999). A Bayesian approach, with some similarity to the Black-Litterman model, to portfolio selection using higher moments has been proposed by Harvey et al. (2010).

KEY POINTS

- Classical mean-variance optimization is sensitive to estimation error and small changes in the inputs.
- There are four different approaches to make the classical mean-variance framework more robust: (1) improve the accuracy of the inputs; (2) use constraints for the portfolio weights; (3) use portfolio resampling to calculate the portfolio weights; and (4) apply the robust optimization framework to the portfolio allocation process.
- Typically, errors in the expected returns are about 10 times more important than errors in the covariance matrix, and errors in the variances are about twice as important as errors in the covariances.
- Estimates of expected return and covariances can be improved by using shrinkage estimation. Shrinkage is a form of averaging different estimators. The shrinkage estimator typically consists of three components: (1) an estimator with little or no structure; (2) an

estimator with a lot of structure (the shrinkage target); and (3) the shrinkage intensity.

- Jorion's shrinkage estimator for the expected return shrinks toward the return of the global minimum variance portfolio.
- The sample covariance matrix should not be used as an input to the mean-variance problem. By shrinking it toward the covariance matrix with constant correlations, its quality will be improved.
- The Black-Litterman model combines an investor's views with the market equilibrium.
- The Black-Litterman expected return is a confidence weighted linear combination of market equilibrium and the investor's views. The confidence in the views and in market equilibrium determines the relative weighting.
- Factor models as well as simple ranking models can be simultaneously incorporated into the Black-Litterman model.

NOTES

1. See Broadie (1993).
2. We are grateful to Axioma Inc. for providing us with this example. Previously, it has appeared in Ceria and Stubbs (2005).
3. See Best and Grauer (1991, 1992).
4. See Chopra and Ziemba (1993) and Kallberg and Ziemba (1984).
5. See, for example, Frost and Savarino (1988), Chopra (1991), and Grauer and Shen (2000).
6. The relationship to information theory is based upon the premise that the diversification indicators are generalized entropies. See Curado and Tsallis (1991).
7. See, for example, Michaud (1998), Jorion (1992), and Scherer (2002).
8. See Goldfarb and Iyengar (2003).
9. Many similar approaches have been proposed. For example, see Jobson and Korkie (1981) and Frost and Savarino (1986).
10. See, for example, Michaud (1998), Jorion (1986), and Larsen and Resnick (2001).
11. Elton, Gruber, and Urich (1978) proposed the single factor model for purposes of co-

variance estimation. They show that this approach leads to (1) better forecasts of the covariance matrix; (2) more stable portfolio allocations over time; and (3) more diversified portfolios. They also find that the average correlation coefficient is a good forecast of the future correlation matrix.

12. Although straightforward to implement, the optimal shrinkage intensity, w , is a bit tedious to write down mathematically. Let us denote by $r_{i,t}$ the return on security i during period t , $1 \leq i \leq N$, $1 \leq t \leq T$,

$$\bar{r}_i = \frac{1}{T} \sum_{t=1}^T r_{i,t} \quad \text{and}$$

$$\hat{\sigma}_{ij} = \frac{1}{T-1} \sum_{t=1}^T (r_{i,t} - \bar{r}_i)(r_{j,t} - \bar{r}_j)$$

Then the optimal shrinkage intensity is given by the formula

$$w = \max \left\{ 0, \min \left\{ \frac{\hat{\kappa}}{T}, 1 \right\} \right\}$$

where

$$\hat{\kappa} = \frac{\hat{\pi} - \hat{c}}{\hat{\gamma}}$$

and the parameters, $\hat{\pi}$, \hat{c} , $\hat{\gamma}$, are computed as follows. First, $\hat{\pi}$ is given by

$$\hat{\pi} = \sum_{i,j=1}^N \hat{\pi}_{ij}$$

where

$$\hat{\pi}_{ij} = \frac{1}{T} \sum_{t=1}^T ((r_{i,t} - \bar{r}_i)(r_{j,t} - \bar{r}_j) - \hat{\sigma}_{ij})^2$$

Second, \hat{c} is given by

$$\hat{c} = \sum_{i=1}^N \hat{\pi}_{ii} + \sum_{\substack{i=1 \\ i \neq j}}^N \frac{\hat{\rho}}{2} \left(\sqrt{\hat{\rho}_{ii}/\hat{\rho}_{ii}} \hat{\nu}_{i,jj} + \sqrt{\hat{\rho}_{ii}/\hat{\rho}_{ii}} \hat{\nu}_{jj,ii} \right)$$

where

$$\vartheta_{ii,jj} = \frac{1}{T} \sum_{t=1}^T [((r_{i,t} - \bar{r}_i)^2 - \hat{\sigma}_{ii}) \times ((r_{i,t} - \bar{r}_i)(r_{j,t} - \bar{r}_j) - \hat{\sigma}_{ij})]$$

Finally, $\hat{\gamma}$ is given by

$$\hat{\gamma} = \|C - C_{CC}\|_F^2$$

where $\|\cdot\|_F$ denotes the Frobenius norm defined by

$$\|A\|_F = \sqrt{\sum_{i,j=1}^N a_{ij}^2}$$

13. A predecessor to the Black-Litterman model is the so-called Treynor-Black model. In this model, an investor's portfolio is shown to consist of two parts: (1) a passive portfolio/positions held purely for the purpose of mimicking the market portfolio, and (2) an active portfolio/positions based on the investor's return/risk expectations. This somewhat simpler model relies on the assumption that returns of all securities are related only through the variation of the market portfolio (Sharpe's diagonal model). See Treynor and Black (1973).
14. For simplicity, we consider only equity securities. Extending this model to other assets classes such as bonds and currencies is fairly straightforward.

Two comments about the above two relationships are of importance:

1. As it may be difficult to accurately estimate expected returns, practitioners use other techniques. One is that of reverse optimization, also referred to as the technique of implied expected returns. The technique simply uses the expression $\Pi = \delta \Sigma \mathbf{w}$ to calculate the expected return vector given the market price of risk δ , the covariance matrix Σ , and the market capitalization weights \mathbf{w} . The technique was first introduced by Sharpe (1974) and Fisher (1975) and is an impor-

tant component of the Black-Litterman model.

2. We note that $E(R_M) - R_f$ is the market risk premium (or the equity premium) of the universe of assets considered. As pointed out by Herold (2005) and Idzorek (2005), using a market proxy with different risk-return characteristics than the market capitalization weighted portfolio for determining the market risk premium may lead to nonintuitive expected returns. For example, using a market risk premium based on the S&P 500 for calculating the implied equilibrium return vector for the NASDAQ 100 should be avoided.
15. See, for example, Black and Litterman (1992) and Litterman (2003).

Bond Valuation

Basics of Bond Valuation

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

STEVEN V. MANN, PhD
Professor of Finance, Moore School of Business, University of South Carolina

Abstract: The value of any financial asset is the present value of its expected future cash flows. To value a bond, one must be able estimate the bond's remaining cash flows and identify the appropriate discount rate(s). The traditional approach to bond valuation is to discount every cash flow with the same discount rate. Simply put, the relevant yield curve used in valuation is assumed to be flat. This approach permits opportunities for arbitrage. Alternatively, the arbitrage-free valuation approach starts with the premise that a bond should be viewed as a portfolio or package of zero-coupon bonds. Moreover, each of the bond's cash flows is valued using a unique discount rate that depends on the shape of the yield curve and when the cash flow is delivered in time. The relevant set of discount rates (that is, spot rates) is derived from the Treasury yield curve and when used to value risky bonds augmented with a spread.

Valuation is the process of determining the fair value of a financial asset. In this entry, we will explain the general principles of bond valuation. Our focus will be on how to value *option-free bonds* (that is, bonds that are not callable, puttable, or convertible). A special analytical framework is required to value more complex bond structures such as bonds that are callable or puttable and mortgage-backed and certain asset-backed securities.

GENERAL PRINCIPLES OF BOND VALUATION

The fundamental principle of valuation is that the value of any financial asset is equal to the present value of its expected future cash flows.

This principle holds for any financial asset from zero-coupon bonds to interest rate swaps. Thus, the valuation of a financial asset involves the following three steps:

- Step 1:* Estimate the expected future cash flows.
- Step 2:* Determine the appropriate interest rate or interest rates that should be used to discount the cash flows.
- Step 3:* Calculate the present value of the expected future cash flows found in Step 1 by using the appropriate interest rate or interest rates determined in Step 2.

Estimating Cash Flows

Cash flow is simply the cash that is expected to be received in the future from owning a

financial asset. For a fixed income security, it does not matter whether the cash flow is interest income or repayment of principal. A security's cash flows represent the sum of each period's expected cash flow. Even if we disregard default, the cash flows for only a few fixed income securities are simple to forecast accurately. U.S. Treasury securities possess this feature since they have known cash flows. While the probability of default of the U.S. government is not zero, it is close enough to that threshold to be safely ignored. Besides, if the U.S. government ever does default, we will have other things to worry about than valuing bonds. For Treasury coupon securities, the cash flows consist of the coupon interest payments every six months up to and including the maturity date and the principal repayment at the maturity date.

Many fixed income securities have features that make estimating their cash flows problematic. These features may include one or more of the following:

1. The issuer or the investor has the option to change the contractual due date of the repayment of the principal.
2. The coupon and/or principal payment is reset periodically based on a formula that depends on one or more market variables (e.g., interest rates, inflation rates, exchange rates, etc.).
3. The investor has the choice to convert or exchange the security into common stock or some other financial asset.

Callable bonds, putable bonds, mortgage-backed securities, and asset-backed securities are examples of (1). Floating-rate securities and Treasury Inflation Protected Securities (TIPS) are examples of (2). Convertible bonds and exchangeable bonds are examples of (3).¹

For securities that fall into the first category, a key factor determining whether the owner of the option (either the issuer of the security or the investor) will exercise the option to alter the security's cash flows is the level of interest rates

in the future relative to the security's coupon rate. In order to estimate the cash flows for these types of securities, we must determine how the size and timing of their expected cash flows will change in the future. For example, when estimating the future cash flows of a callable bond, we must account for the fact that when interest rates change, the expected cash flows change. This introduces an additional layer of complexity to the valuation process. For bonds with embedded options, estimating cash flows is accomplished by introducing a parameter that reflects the expected volatility of interest rates.

Determining the Appropriate Interest Rate or Rates

Once we estimate the cash flows for a fixed income security, the next step is to determine the appropriate interest rate for discounting each cash flow. Before proceeding, we pause here to note that we will use the terms "interest rate," "discount rate," and "required yield" interchangeably throughout this entry. The interest rate used to discount a particular security's cash flows will depend on three basic factors: (1) the level of benchmark interest rates (that is, U.S. Treasury rates); (2) the risks that the market perceives the securityholder is exposed to; and (3) the compensation the market expects to receive for these risks.

The minimum interest rate that an investor should require is the yield available in the marketplace on a default-free cash flow. For bonds with dollar-denominated cash flows, yields on U.S. Treasury securities serve as benchmarks for default-free interest rates. For now, we can think of the minimum interest rate that investors require as the yield on a comparable maturity Treasury security.

The additional compensation or spread over the yield on the Treasury issue that investors will require reflects the additional risks the investor faces by acquiring a security that is not issued by the U.S. government. These risks include default risk, liquidity risk, and the risks

associated with any embedded options. These yield spreads will depend not only on the risks an individual issue is exposed to but also on the level of Treasury yields, the market's risk aversion, the business cycle, and so forth.

For each cash flow estimated, the same interest rate can be used to calculate the present value. This is the traditional approach to valuation and it serves as a useful starting point for our discussion. We discuss the traditional approach in the next section and use a single interest rate to determine present values. By doing this, however, we are implicitly assuming that the yield curve is flat. Since the yield curve is almost never flat and a coupon bond can be thought of as a package of zero-coupon bonds, it is more appropriate to value each cash flow using an interest rate specific to that cash flow. After the traditional approach to valuation is discussed, we will explain the proper approach to valuation using multiple interest rates and demonstrate why this must be the case.

Discounting the Expected Cash Flows

Once the expected (estimated) cash flows and the appropriate interest rate or interest rates that should be used to discount the cash flows are determined, the final step in the valuation process is to value the cash flows. The present value of an expected cash flow to be received t years from now using a discount rate i is:

$$\text{Present value}_t = \frac{\text{Expected cash flow in period}^t}{(1 + i)^t}$$

The value of a financial asset is then the sum of the present value of all the expected cash flows. Specifically, assuming that there are N expected cash flows:

$$\text{Value} = \text{Present value}_1 + \text{Present value}_2 + \dots + \text{Present value}_N$$

Determining a Bond's Value

Determining a bond's value involves computing the present value of the expected future cash flows using a discount rate that reflects market interest rates and the bond's risks. A bond's cash flows come in two forms—coupon interest payments and the repayment of principal at maturity. In practice, many bonds deliver semiannual cash flows. Fortunately, this does not introduce any complexities into the calculation. Two simple adjustments are needed. First, we adjust the coupon payments by dividing the annual coupon payment by 2. Second, we adjust the discount rate by dividing the annual discount rate by 2. The time period t in the present value expression is treated in terms of 6-month periods as opposed to years.

To illustrate the process, let's value a 4-year, 6% coupon bond with a maturity value of \$100. The coupon payments are \$3 ($0.06 \times \$100/2$) every six months for the next eight periods. In addition, on the maturity date, the investor receives the repayment of principal (\$100). The value of a nonamortizing bond can be divided in two components: (1) the present value of the coupon payments (that is, an annuity) and (2) the present value of the maturity value (that is, a lump sum). Therefore, when a single discount rate is employed, a bond's value can be thought of as the sum of two present values—an annuity and a lump sum.

The adjustment for the discount rate is easy to accomplish but tricky to interpret. For example, if an annual discount rate of 6% is used, how do we obtain the semiannual discount rate? We will simply use one-half the annual rate, 3.0% ($6\%/2$). How can this be? A 3.0% semiannual rate is not a 6% effective annual rate. As we will see later in this entry, the convention in the bond market is to quote annual interest rates that are just double the semiannual rates. This convention will be explained more fully later when we discuss yield to maturity. For now, accept on faith that one-half the discount rate is used as a semiannual discount rate in the balance of the entry.

We now have everything in place to value a semiannual coupon-paying bond. The present value of an annuity is equal to:

$$\text{Annuity payment} \times \left[\frac{1 - \frac{1}{(1+r)^{\text{no. of years}}}}{r} \right]$$

where r is the *annual* discount rate.

Applying this formula to a semiannual-pay bond, the annuity payment is one half the annual coupon payment and the number of periods is double the number of years to maturity. Accordingly, the present value of the coupon payments can be expressed as:

$$\begin{aligned} &\text{Semiannual coupon payment} \\ &\times \left[\frac{1 - \frac{1}{(1+i)^{\text{no. of years} \times 2}}}{i} \right] \end{aligned}$$

where i is the semiannual discount rate ($r/2$). Notice that in the formula, for the number of periods we use the number of years multiplied by 2 since a period in our illustration is six months.

The present value of the maturity value is just the present value of a lump sum and is equal to:

$$\begin{aligned} &\text{Present value of the maturity value} \\ &= \frac{\$100}{(1+i)^{\text{No. of years} \times 2}} \end{aligned}$$

We will illustrate the calculation by valuing our 4-year, 6% coupon bond assuming that the relevant discount rate is 7%. The data are summarized below:

Semiannual coupon payment = \$3 (per \$100 of par value)

Semiannual discount rate (i) = 3.5% ($7\%/2$)

Number of years to maturity = 4

The present value of the coupon payments is:

$$\$3 \times \left[\frac{1 - \frac{1}{(1.035)^{4 \times 2}}}{0.035} \right] = \$20.6219$$

This number tells us that the coupon payments contribute \$20.6219 to the bond's value.

The present value of the maturity value is:

$$\begin{aligned} \text{Present value of the maturity value} &= \frac{\$100}{(1.035)^{4 \times 2}} \\ &= \$75.9412 \end{aligned}$$

This number (\$75.9412) tells us how much the maturity value contributes to the bond's value. The bond's value is then \$96.5631 (\$20.6219 + \$75.9412). The price is less than par value and the bond is said to be trading at a discount. This will occur when the fixed coupon rate a bond offers (6%) is less than the required yield demanded by the market (the 7% discount rate). A discount bond has an inferior coupon rate relative to new comparable bonds being issued at par so its price must drop so as to offer the required yield of 7%. If the discount bond is held to maturity, the investor will experience a capital gain that just offsets the lower current coupon rate so that it appears equally attractive to new comparable bonds issued at par.

Suppose instead of a 7% discount rate, a 5% discount rate is used. This discount rate is less than the coupon rate on the bond (6%). It can be shown that the present value of the coupon payments is \$21.5104 and the present value of the maturity value is \$82.0747. Thus, the bond's value in this case is \$103.5851. That is, the price is greater than par value and the bond is said to be trading at a premium. This will occur when the fixed coupon rate a bond offers (6%) is greater than the required yield demanded by the market (the 5% discount rate). Accordingly, a premium bond carries a higher coupon rate than new bonds (otherwise the same) being issued today at par so the price will be bid up and the required yield will fall until it equals 5%. If the premium bond is held to maturity, the investor will experience a capital loss that just offsets the benefits of the higher coupon rate so that it will appear equally attractive to new comparable bonds issued at par.

Finally, let's suppose that the discount rate is equal to the coupon rate. That is, suppose that

the discount rate is 6%. It can be shown that the present value of the coupon payments is \$21.0591 and the present value of the maturity value is \$78.9409. Thus, the bond's value in this case is \$100 or par value. Thus, when a bond's coupon rate is equal to the discount rate, the bond will trade at par value. Note that the preceding statement is strictly true only when a bond is valued on its coupon payment dates.

Valuing a Zero-Coupon Bond

For a zero-coupon bond, there is only one cash flow—the repayment of principal at maturity. The value of a zero-coupon bond that matures N years from now is:

$$\frac{\text{Maturity value}}{(1 + i)^{N \times 2}}$$

where i is the semiannual discount rate.

The expression presented above states that the price of a zero-coupon bond is simply the present value of the maturity value. In the present value computation, why is the number of periods used for discounting rather than the number of years to the bond's maturity when there are no semiannual coupon payments? We do this in order to make the valuation of a zero-coupon bond consistent with the valuation of a coupon bond. In other words, both coupon and zero-coupon bonds are valued using semiannual discounting rates.

To illustrate, the value of a 10-year zero-coupon bond with a maturity value of \$100 discounted at a 6.4% interest rate is \$53.2606, as presented below:

$$\begin{aligned} i &= 0.032 = (0.064/2) \\ N &= 10 \\ \frac{\$100}{(1.032)^{10 \times 2}} &= \$53.2606 \end{aligned}$$

Valuing a Bond between Coupon Payments

In our discussion of bond valuation to this point, we have assumed that the bonds are valued on their coupon payment dates (that is, the next coupon payment is one full period away).

For bonds with semiannual coupon payments, this occurs only twice a year. Our task now is to describe how bonds are valued on the other 363 days (or 364 days) of the year.

In order to value a bond with a settlement date between coupon payments, we must answer three questions. First, how many days are there until the next coupon payment date? The answer depends on the day count convention for the bond being valued. Second, how should we compute the present value of the cash flows received over the fractional period? Third, how much must the buyer compensate the seller for the coupon earned over the fractional period? This amount is accrued interest. We will answer these three questions in order to determine the full price and the clean price of a coupon bond. For a more detailed discussion of these issues for not only U.S. bonds but bonds traded in other countries, see Krgin (2002).

Computing the Full Price When valuing a bond purchased with a settlement date between coupon payment dates, the first step is to determine the fractional periods between the settlement date and the next coupon date. Using the appropriate day count convention, this is determined as follows:

$$w \text{ periods} = \frac{\text{Days between settlement date and next coupon payment date}}{\text{Days in the coupon period}}$$

Then the present value of each expected future cash flow to be received t periods from now using a discount rate i assuming the next coupon payment is w periods from now (settlement date) is:

$$\text{Present value}_t = \frac{\text{Expected cash flow}}{(1 + i)^{t-1+w}}$$

Note for the first coupon payment subsequent to the settlement date, $t = 1$ so the exponent is just w . This procedure for calculating the present value when a bond is purchased between coupon payments is called the "Street

method." In the Street method, as can be seen in the previous expression, coupon interest is compounded over the fractional period w .²

To illustrate the calculation, suppose that a U.S. Treasury note maturing on December 31, 2007, was purchased with a settlement date of November 22, 2006. This note's coupon rate was 4.375 and it had coupon payment dates of June 30 and December 31. As a result, the next coupon payment was December 31, 2006, while the previous coupon payment was paid on June 30, 2006. There were three cash flows remaining and they were to be delivered on December 31, 2006, June 30, 2007, and December 31, 2007. The final cash flow represented the last coupon payment and the maturity value of \$100. Also assume the following:

1. Actual/actual day count convention
2. 39 days between the settlement date and the next coupon payment date
3. 184 days in the coupon period

Then w is 0.2120 periods (39/184). The present value of each cash flow assuming that each is discounted at a 4.9% annual discount rate is

$$\begin{aligned} \text{Period 1: Present value}_1 &= \frac{\$2.1875}{(1.0245)^{0.2120}} \\ &= \$2.1761 \end{aligned}$$

$$\begin{aligned} \text{Period 2: Present value}_2 &= \frac{\$2.1875}{(1.0245)^{1.2120}} \\ &= \$2.1243 \end{aligned}$$

$$\begin{aligned} \text{Period 3: Present value}_3 &= \frac{\$102.1875}{(1.0245)^{2.2120}} \\ &= \$96.8498 \end{aligned}$$

The sum of the present values of the cash flows is \$101.1502. This price is referred to as the *full price* (or the *dirty price*).

It is the full price the bond's buyer pays the seller at delivery. However, the very next cash flow received and included in the present value calculation was not earned by the bond's buyer. A portion of the next coupon payment is the accrued interest. Accrued interest is the portion of a bond's next coupon payment that the bond's

seller is entitled to depending on the amount of time the bond was held by the seller. Recall that the buyer recovers the accrued interest when the next coupon payment is delivered.

Computing the Accrued Interest and the Clean Price The last step in this process is to find the bond's value without accrued interest (called the *clean price* or simply price). To do this, the accrued interest must be computed. The first step is to determine the number of days in the accrued interest period (that is, the number of days between the last coupon payment date and the settlement date) using the appropriate day count convention. For ease of exposition, we will assume in the example that follows that the actual/actual calendar is used. We will also assume there are only two bondholders in a given coupon period—the buyer and the seller.

As an illustration, we return to the previous example with the 4.375% coupon Treasury note. Since there were 184 days in the coupon period and 39 days from the settlement date to the next coupon period, there were 145 days (184–39) in the accrued interest period. Therefore, the percentage of the next coupon payment that is accrued interest is:

$$\frac{145}{184} = 0.7880 = 78.80\%$$

Of course, this is the same percentage found by simply subtracting w from 1. In our example, w was 0.2120. Then, $1 - 0.2120 = 0.7880$.

Given the value of w , the amount of accrued interest (AI) is equal to:

$$\text{AI} = \text{Semiannual coupon payment} \times (1 - w)$$

Accordingly, using a 4.375 Treasury note with a settlement date of November 22, 2006, the portion of the next coupon payment that was accrued interest was:

$$\$2.1875 \times (1 - 0.7880) = \$1.7238 \text{ (per \$100 of par value)}$$

Once we know the full price and the accrued interest, we can determine the clean price. The

clean price is the price quoted in the market and represents the bond's value to the new bondholder. The clean price is computed as follows:

$$\text{Clean price} = \text{Full price} - \text{Accrued interest}$$

In our illustration, the clean price is:

$$\$99.43 = \$101.1502 - \$1.7238$$

Note that in computing the full price, the present value of the next coupon payment is computed. However, the buyer pays the seller the accrued interest now despite the fact that it will not be recovered until the next coupon payment date. To make this concrete, suppose one sells a bond such that the settlement date is halfway between the coupon payment dates. In this case $w = 0.50$. Accordingly, the seller will be entitled to one-half of the next coupon payment which would not otherwise be received for another three months. Thus, when calculating the clean price, we subtract "too much" accrued interest—one-half the coupon payment rather than the present value of one-half the coupon payment. Of course, this is the market convention for calculating accrued interest but it does introduce a curious twist in bond valuation.

The Price/Discount Rate Relationship

An important general property of present value is that the higher (lower) the discount rate, the lower (higher) the present value. Since the value of a security is the present value of the expected future cash flows, this property carries over to the value of a security: The higher (lower) the discount rate, the lower (higher) a security's value. We can summarize the relationship between the coupon rate, the required market yield, and the bond's price relative to its par value as follows:

$$\begin{aligned} \text{Coupon rate} &= \text{Yield required by market} \\ &\Rightarrow \text{Price} = \text{Par value} \end{aligned}$$

$$\begin{aligned} \text{Coupon rate} &< \text{Yield required by market} \\ &\Rightarrow \text{Price} < \text{Par value (discount)} \end{aligned}$$

$$\begin{aligned} \text{Coupon rate} &> \text{Yield required by market} \\ &\Rightarrow \text{Price} > \text{Par value (premium)} \end{aligned}$$

This agrees with what we found for the 4-year, 6% coupon bond:

Coupon Rate	Yield Required by Market	Price	Bond Trading at
6%	7%	\$96.5631	Discount
6%	5%	\$103.5851	Premium
6%	6%	\$100.0000	Par

Figure 1 depicts this inverse relationship between an option-free bond's price and its discount rate (that is, required yield). There are two things to infer from the price/discount rate relationship depicted in the figure. First, the relationship is downward sloping. This is simply the inverse relationship between present values and discount rates at work. Second, the relationship is represented as a curve rather than a straight line. In fact, the shape of the curve in Figure 1 is referred to as convex. By convex, it simply means the curve is "bowed in" relative to the origin. This second observation raises two questions about the convex or curved shape of the price/discount rate relationship. First, why is it curved? Second, what is the import of the curvature?

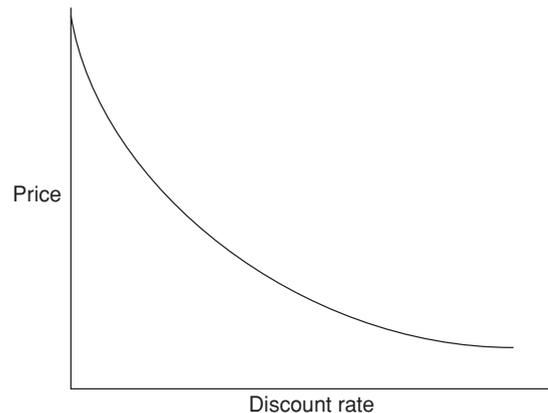

Figure 1 Price/Discount Rate Relationship for an Option-Free Bond

The answer to the first question is mathematical. The answer lies in the denominator of the bond pricing formula. Since we are raising one plus the discount rate to powers greater than one, it should not be surprising that the relationship between the level of the price and the level of the discount rate is not linear.

As for the importance of the curvature to bond investors, let's consider what happens to bond prices in both falling and rising interest rate environments. First, what happens to bond prices as interest rates fall? The answer is obvious—bond prices rise. How about the rate at which they rise? If the price/discount rate relationship was linear, as interest rates fell, bond prices would rise at a constant rate. However, the relationship is not linear, it is curved and curved inward. Accordingly, when interest rates fall, bond prices increase at an increasing rate. Now, let's consider what happens when interest rates rise. Of course, bond prices fall. How about the rate at which bond prices fall? Once again, if the price/discount rate relationship were linear, as interest rates rose, bond prices would fall at a constant rate. Since it curved inward, when interest rates rise, bond prices decrease at a decreasing rate.

Time Path of Bond

As a bond moves towards its maturity date, its value changes. More specifically, assuming that the discount rate does not change, a bond's value:

1. Decreases over time if the bond is selling at a premium.
2. Increases over time if the bond is selling at a discount.
3. Is unchanged if the bond is selling at par value.

With respect to the last property, we are assuming the bond is valued on its coupon anniversary dates.

At the maturity date, the bond's value is equal to its par or maturity value. So, as a bond's

maturity approaches, the price of a discount bond will rise to its par value and a premium bond will fall to its par value—a characteristic sometimes referred to as *pull to par value*.

ARBITRAGE-FREE BOND VALUATION

The traditional approach to valuation is to discount every cash flow of a fixed income security using the same interest or discount rate. The fundamental flaw of this approach is that it views each security as the same package of cash flows. For example, consider a 5-year U.S. Treasury note with a 6% coupon rate. The cash flows per \$100 of par value would be 9 payments of \$3 every six months and \$103 ten 6-month periods from now. The traditional practice would discount every cash flow using the same discount rate regardless of when the cash flows are delivered in time and the shape of the yield curve. Finance theory tells us that any security should be thought of as a package or portfolio of zero-coupon bonds.

The proper way to view the 5-year 6% coupon Treasury note is as a package of zero-coupon instruments whose maturity value is the amount of the cash flow and whose maturity date coincides with the date the cash flow is to be received. Thus, the 5-year 6% coupon Treasury issue should be viewed as a package of 10 zero-coupon instruments that mature every six months for the next five years. This approach to valuation does not allow a market participant to realize an arbitrage profit by breaking apart or "stripping" a bond and selling the individual cash flows (that is, stripped securities) at a higher aggregate value than it would cost to purchase the security in the market. Simply put, arbitrage profits are possible when the sum of the parts is worth more than the whole or vice versa. Because this approach to valuation precludes arbitrage profits, we refer to it as the *arbitrage-free valuation approach*.

By viewing any security as a package of zero-coupon bonds, a consistent valuation

framework can be developed. Viewing a security as a package of zero-coupon bonds means that two bonds with the same maturity and different coupon rates are viewed as different packages of zero-coupon bonds and valued accordingly. Moreover, two cash flows that have identical risk delivered at the same time will be valued using the same discount rate even though they are attached to two different bonds.

To implement the arbitrage-free approach it is necessary to determine the theoretical rate that the U.S. Treasury would have to pay on a zero-coupon Treasury security for each maturity. We say “theoretical” because other than U.S. Treasury bills, the Treasury does not issue zero-coupon bonds. Zero-coupon Treasuries are, however, created by dealer firms. The name given to the zero-coupon Treasury rate is the (Treasury) *spot rate*. Our next task is to explain how the Treasury spot rate can be calculated.

Theoretical Spot Rates

The theoretical spot rates for Treasury securities represent the appropriate set of interest or discount rates that should be used to value default-free cash flows. A default-free theoretical spot rate can be constructed from the observed Treasury yield curve or par curve. We will begin our quest of how to estimate spot rates with the par curve.

Par Rates

The raw material for all yield curve analysis is the set of yields on the most recently issued (that is, on-the-run) Treasury securities. The U.S. Treasury routinely issues 10 securities—the 1-month, 3-month, 6-month, and 1-year bills and the 2-, 3-, 5-, 7-, and 10-year notes, and a 30-year bond. These on-the-run Treasury issues are default risk-free and trade in one of the most liquid and efficient secondary markets in the world. Because of these characteristics, historically Treasury yields serve as a reference benchmark for risk-free rates which are used for

pricing other securities. However, other benchmarks such as the swap curve are now used but the principles of valuation remain unchanged.

In practice, however, the observed yields for the on-the-run Treasury coupon issues are not usually used directly. Instead, the coupon rate is adjusted so that the price of the issue would be the par value. Accordingly, the par yield curve is the adjusted on-the-run Treasury yield curve where coupon issues are at par value and the coupon rate is therefore equal to the yield to maturity. The exception is for the 6-month Treasury bills; the bond-equivalent yield for this issue is already the spot rate.

Deriving a par curve from a set of points starting with the yield on the 6-month bill and ending the yield on the 30-year bond is not a trivial matter. The end result is a curve that tells us “if the Treasury were to issue a security today with a maturity equal to say 12 years, what coupon rate would the security have to pay in order to sell at par?” Some analysts contend that estimating the par curve with only the yields of the on-the-run Treasuries uses too little information that is available from the market. In particular, one must estimate the back-end of the yield curve with only one security, that is, the 30-year bond. Some analysts prefer to use the on-the-run Treasuries and selected off-the-run Treasuries.

In summary, a par rate is the average discount rate of many cash flows (those of a par bond) over many periods. This begs the question, “the average of what?” As we will see, par rates are complicated averages of the implied spot rates. Thus, in order to uncover the spot rates, we must find a method to “break apart” the par rates. There are several approaches that are used in practice.³ The approach that we describe below for creating a theoretical *spot rate curve* is called *bootstrapping*.

Bootstrapping the Spot Rate Curve

Bootstrapping begins with the par curve. To illustrate bootstrapping, we will use the Treasury

Table 1 Hypothetical Treasury Par Yield Curve

Period	Years	Annual Yield to Maturity (BEY) (%)*	Price	Spot Rate (BEY) (%)*
1	0.5	3.00	—	3.0000
2	1.0	3.30	—	3.3000
3	1.5	3.50	100.00	3.5053
4	2.0	3.90	100.00	3.9164
5	2.5	4.40	100.00	4.4376
6	3.0	4.70	100.00	4.7520
7	3.5	4.90	100.00	4.9622
8	4.0	5.00	100.00	5.0650
9	4.5	5.10	100.00	5.1701
10	5.0	5.20	100.00	5.2772
11	5.5	5.30	100.00	5.3864
12	6.0	5.40	100.00	5.4976
13	6.5	5.50	100.00	5.6108
14	7.0	5.55	100.00	5.6643
15	7.5	5.60	100.00	5.7193
16	8.0	5.65	100.00	5.7755
17	8.5	5.70	100.00	5.8331
18	9.0	5.80	100.00	5.9584
19	9.5	5.90	100.00	6.0863
20	10.0	6.00	100.00	6.2169

*The yield to maturity and the spot rate are annual rates. They are reported as bond-equivalent yields. To obtain the semiannual yield or rate, one half the annual yield or annual rate is used.

par curve shown in Table 1. The par yield curve shown extends only out to 10 years. Our objective is to show how the values in the last column of the table (labeled “Spot Rate”) are obtained. Throughout the analysis and illustrations to come, it is important to remember the basic principle is that the value of the Treasury coupon security should be equal to the value of the package of zero-coupon Treasury securities that duplicates the coupon bond’s cash flows.

The key to this process is the existence of the Treasury strips market. A government securities dealer has the ability to take apart the cash flows of a Treasury coupon security (that is, strip the security) and create zero-coupon securities. These zero-coupon securities, which are called Treasury strips, can be sold to investors. At what interest rate or yield can these Treasury strips be sold to investors? The answer is

they can be sold at the Treasury spot rates. If the market price of a Treasury security is less than its value after discounting with spot rates (that is, the sum of the parts is worth more than the whole), then a dealer can buy the Treasury security, strip it, and sell off the Treasury strips so as to generate greater proceeds than the cost of purchasing the Treasury security. The resulting profit is an arbitrage profit.

Before we proceed to our illustration of bootstrapping, a very sensible question must be addressed. Specifically, if Treasury strips are in effect zero-coupon Treasury securities, why not use strip rates (that is, the rates on Treasury strips) as our spot rates? In other words, why must we estimate theoretical spot rates via bootstrapping using yields from Treasury bills, notes, and bonds when we already have strip rates conveniently available? There are three major reasons. First, although Treasury strips are actively traded, they are not as liquid as on-the-run Treasury bills, notes, and bonds. As a result, Treasury strips have some liquidity risk for which investors will demand some compensation in the form of higher yields. Second, the tax treatment of strips is different from that of Treasury coupon securities. Specifically, the accrued interest on strips is taxed even though no cash is received by the investor. Thus, they are negative cash flow securities to taxable entities, and, as a result, their yield reflects this tax disadvantage. Finally, there are maturity sectors where non-U.S. investors find it advantageous to trade off yield for tax advantages associated with a strip. Specifically, certain non-U.S. tax authorities allow their citizens to treat the difference between the maturity value and the purchase price as a capital gain and tax this gain at a favorable tax rate. Some will grant this favorable treatment only when the strip is created from the principal rather than the coupon. For this reason, those who use Treasury strips to represent theoretical spot rates restrict the issues included to coupon strips.

Now let’s see how to generate the spot rates. Consider the 6-month Treasury security in

Table 1. This security is a Treasury bill and is issued as a zero-coupon instrument. Therefore, the annualized bond-equivalent yield (not the bank discount yield) of 3.00% for the 6-month Treasury security is equal to the 6-month spot rate. Using the yield on the 1-year bill, we use 3.3% as the 1-year spot rate. Given these two spot rates, we can compute the spot rate for a theoretical 1.5-year zero-coupon Treasury. The value of a theoretical 1.5-year Treasury should equal the present value of the three cash flows from the 1.5-year coupon Treasury, where the yield used for discounting is the spot rate corresponding to the time of receipt of the cash flow. Since all the coupon bonds are selling at par, as explained in the previous section, the yield to maturity for each bond is the coupon rate. Using \$100 as par, the cash flows for the 1.5-year coupon Treasury are:

0.5 year	$0.035 \times \$100 \times 0.5$	= \$1.75
1.0 year	$0.035 \times \$100 \times 0.5$	= \$1.75
1.5 years	$0.035 \times \$100 \times 0.5 + 100$	= \$101.75

The present value of the cash flows is then:

$$\frac{1.75}{(1+z_1)^1} + \frac{1.75}{(1+z_2)^2} + \frac{101.75}{(1+z_3)^3}$$

where

- z_1 = one-half the annualized 6-month theoretical spot rate
- z_2 = one-half the 1-year theoretical spot rate
- z_3 = one-half the 1.5-year theoretical spot rate

Since the 6-month spot rate is 3% and the 1-year spot rate is 3.30%, we know that:

$$z_1 = 0.0150 \quad \text{and} \quad z_2 = 0.0165$$

We can compute the present value of the 1.5-year coupon Treasury security as:

$$\begin{aligned} \frac{1.75}{(1+z_1)^1} + \frac{1.75}{(1+z_2)^2} + \frac{101.75}{(1+z_3)^3} &= \frac{1.75}{(1.015)^1} \\ &+ \frac{1.75}{(1.0165)^2} + \frac{101.75}{(1+z_3)^3} \end{aligned}$$

Since the price of the 1.5-year coupon Treasury security is equal to its par value (see

Table 1), the following relationship must hold

$$\frac{1.75}{(1.015)^1} + \frac{1.75}{(1.0165)^2} + \frac{101.75}{(1+z_3)^3} = 100$$

If we had not been working with a par yield curve, the equation would have been set to the market price for the 1.5-year issue rather than par value.

Note we are treating the 1.5 year par bond as if it were a portfolio of three zero-coupon bonds. Moreover, each cash flow has its own discount rate that depends on when the cash flow is delivered in the future and the shape of the yield curve. This is in sharp contrast to the traditional valuation approach that forces each cash flow to have the same discount rate.

We can solve for the theoretical 1.5-year spot rate as follows:

$$\begin{aligned} 1.7241 + 1.6936 + \frac{101.75}{(1+z_3)^3} &= 100 \\ \frac{101.75}{(1+z_3)^3} &= 96.5822 \\ (1+z_3)^3 &= \frac{101.75}{96.5822} \\ (1+z_3)^3 &= 1.05351 \\ z_3 &= 0.017527 \\ &= 1.7527\% \end{aligned}$$

Doubling this yield we obtain the bond-equivalent yield of 3.5053%, which is the theoretical 1.5-year spot rate. This is the rate that the market would apply to a 1.5-year zero-coupon Treasury security if, in fact, such a security existed. In other words, all Treasury cash flows to be received 1.5 years from now should be valued (that is, discounted) at 3.5053%.

Given the theoretical 1.5-year spot rate, we can obtain the theoretical 2-year spot rate. The cash flows for the 2-year coupon Treasury in Table 1 are:

0.5 year	$0.039 \times \$100 \times 0.5$	= \$1.95
1.0 year	$0.039 \times \$100 \times 0.5$	= \$1.95
1.5 years	$0.039 \times \$100 \times 0.5$	= \$1.95
2.0 years	$0.039 \times \$100 \times 0.5 + 100$	= \$101.95

The present value of the cash flows is then:

$$\frac{1.95}{(1+z_1)^1} + \frac{1.95}{(1+z_2)^2} + \frac{1.95}{(1+z_3)^3} + \frac{101.95}{(1+z_4)^4}$$

where z_4 = one-half of the 2-year theoretical spot rate.

Since the 6-month spot rate, 1-year spot rate, and 1.5-year spot rate are 3.00%, 3.30%, and 3.5053%, respectively, then:

$$z_1 = 0.0150 \quad z_2 = 0.0165 \quad z_3 = 0.017527$$

Therefore, the present value of the 2-year coupon Treasury security is:

$$\begin{aligned} & \frac{1.95}{(1.0150)^1} + \frac{1.95}{(1.0165)^2} + \frac{1.95}{(1.017527)^3} \\ & + \frac{101.95}{(1+z_4)^4} = 100 \end{aligned}$$

Since the price of the 2-year coupon Treasury security is equal to par, the following relationship must hold:

$$\begin{aligned} & \frac{1.95}{(1.0150)^1} + \frac{1.95}{(1.0165)^2} + \frac{1.95}{(1.017527)^3} \\ & + \frac{101.95}{(1+z_4)^4} = 100 \end{aligned}$$

We can solve for the theoretical 2-year spot rate as follows:

$$\begin{aligned} \frac{101.95}{(1+z_4)^4} &= 94.3407 \\ (1+z_4)^4 &= \frac{101.95}{94.3407} \\ z_4 &= 0.019582 = 1.9582\% \end{aligned}$$

Doubling this yield, we obtain the theoretical 2-year spot rate bond-equivalent yield of 3.9164%.

One can follow this approach sequentially to derive the theoretical 2.5-year spot rate from the calculated values of z_1 , z_2 , z_3 , and z_4 (the 6-month, 1-year, 1.5-year, and 2-year rates), and the price and coupon of the 2.5-year bond in Table 1. Further, one could derive theoretical spot rates for the remaining 15 half-yearly rates. The spot rates thus obtained are shown in the last column of Table 1. They represent the term structure of default-free spot rate for maturities up to 10 years at the particular time to which the bond price quotations refer.

Let us summarize to this point. We started with the par curve which is constructed using the adjusted yields from the on-the-run Treasuries. A par rate is the average discount rate of many cash flows over many periods. Specifically, par rates are complicated averages of spot rates. The spot rates are uncovered from par rates via bootstrapping. A spot rate is the average discount rate of a single cash flow over many periods. It appears that spot rates are also averages. Spot rates are averages of one or more forward rates.

Valuation Using Treasury Spot Rates

To illustrate how Treasury spot rates are used to compute the arbitrage-free value of a Treasury security, we will use the hypothetical Treasury spot rates shown in the fourth column of Table 2 to value an 8%, 10-year Treasury security. The present value of each period's cash flow is shown in the fifth column. The sum of the present values is the arbitrage-free value for the Treasury security. For the 8%, 10-year Treasury it is \$107.0018.

Reason for Using Treasury Spot Rates

Thus far, we have simply asserted that the value of a Treasury security should be based on discounting each cash flow using the corresponding Treasury spot rate. But what if market participants value a security using just the yield for the on-the-run Treasury with a maturity equal to the maturity of the Treasury security being valued? Let's see why the value of a Treasury security should trade close to its arbitrage-free value.

Stripping and Arbitrage-Free Valuation

The key to the arbitrage-free valuation approach is the existence of the Treasury strips market. A dealer has the ability to take apart the cash flows of a Treasury coupon security (that is, strip the security) and create zero-coupon

securities. These zero-coupon securities, called Treasury strips, can be sold to investors. At what interest rate or yield can these Treasury strips be sold to investors? They can be sold at the Treasury spot rates. If the market price of a Treasury security is less than its value using the arbitrage-free valuation approach, then a dealer can buy the Treasury security, strip it, and sell off the individual Treasury strips so as to generate greater proceeds than the cost of purchasing the Treasury security. The resulting profit is an arbitrage profit. Since as we will see, the value determined by using the Treasury spot rates does not allow for the generation of an arbitrage profit, this is referred to as an “arbitrage-free” approach.

To illustrate this, suppose that the yield for the on-the-run 10-year Treasury issue is 7.08%. Suppose that the 8% coupon 10-year Treasury issue is valued using the traditional approach based on 7.08%. The value based on discounting all the cash flows at 7.08% is \$106.5141 as shown in the next-to-the-last column in Table 2.

Consider what would happen if the market priced the security at \$106.5141 and that the spot rates are those shown in the fourth column of Table 2. The value based on the Treasury spot rates is \$107.0018 as shown in the fifth column of Table 2. What can the dealer do? The dealer can buy the 8% 10-year issue for \$106.5141, strip it, and sell the Treasury strips at the spot rates shown in Table 2. By doing so, the proceeds that will be received by the dealer are \$107.0018. This results in an arbitrage profit (ignoring transaction costs) of \$0.4877 ($= \$107.0018 - \106.5141). Dealers recognizing this arbitrage opportunity will bid up the price of the 8% 10-year Treasury issue in order to acquire it and strip it. The arbitrage profit will be eliminated when the security is priced at \$107.0018, the value that we said is the arbitrage-free value.

To understand in more detail where this arbitrage profit is coming from, look at the last three columns in Table 2. The sixth column shows how much each cash flow can be sold for by the dealer if it is stripped. The values in this

Table 2 Determination of the Arbitrage-Free Value of an 8% 10-Year Treasury and Arbitrage Opportunity

Period	Years	Arbitrage-Free Value			Arbitrage Opportunity		
		Cash Flow (\$)	Spot Rate (%)	Present Value (\$)	Sell for	Buy for	Arbitrage Profit
1	0.5	4	6.05	3.8826	3.8826	3.8632	0.0193

12	6.0	4	6.53	2.7203	2.7203	2.6349	0.0854
13	6.5	4	6.63	2.6178	2.6178	2.5448	0.0730
14	7.0	4	6.78	2.5082	2.5082	2.4578	0.0504
15	7.5	4	6.79	2.4242	2.4242	2.3738	0.0504
16	8.0	4	6.81	2.3410	2.3410	2.2926	0.0484
17	8.5	4	6.84	2.2583	2.2583	2.2142	0.0441
18	9.0	4	6.93	2.1666	2.1666	2.1385	0.0281
19	9.5	4	7.05	2.0711	2.0711	2.0654	0.0057
20	10.0	104	<u>7.20</u>	<u>51.2670</u>	<u>51.2670</u>	<u>51.8645</u>	<u>-0.5975</u>
			Total	107.0018	107.0018	106.5141	0.4877

column are just those in the fifth column. The next-to-last column shows how much the dealer is effectively purchasing the cash flow for if each cash flow is discounted at 7.08%. The sum of the arbitrage profit from each stripped cash flow is the total arbitrage profit and is contained in the last column.

We have just demonstrated how coupon stripping of a Treasury issue will force the market value to be close to the value as determined by the arbitrage-free valuation approach when the market price is less than the arbitrage-free value (that is, the whole is worth less than the sum of the parts). What happens when a Treasury issue's market price is greater than the arbitrage-free value? Obviously, a dealer will not want to strip the Treasury issue since the proceeds generated from stripping will be less than the cost of purchasing the issue.

When such situations occur, the dealer can purchase a package of Treasury strips so as to create a synthetic Treasury coupon security that is worth more than the same maturity and same coupon Treasury issue. This process is called reconstitution.

The process of stripping and reconstituting ensures that the price of a Treasury issue will not depart materially (depending on transaction costs) from its arbitrage-free value.

Credit Spreads and the Valuation of Non-Treasury Securities

The Treasury spot rates can be used to value any default-free security. For a non-Treasury security, the theoretical value is not as easy to determine. The value of a non-Treasury security is found by discounting the cash flows by the Treasury spot rates plus a yield spread which reflects the additional risks (e.g., default risk, liquidity risks, the risk associated with any embedded options, and so on).

The spot rate used to discount the cash flow of a non-Treasury security can be the Treasury spot rate plus a constant credit spread. For example,

suppose the 6-month Treasury spot rate is 6.05% and the 10-year Treasury spot rate is 7.20%. Also suppose that a suitable credit spread is 100 basis points. Then a 7.05% spot rate is used to discount a 6-month cash flow of a non-Treasury bond and an 8.20% discount rate is used to discount a 10-year cash flow. (Remember that when each semiannual cash flow is discounted, the discount rate used is one-half the spot rate: 3.525% for the 6-month spot rate and 4.10% for the 10-year spot rate.)

The drawback of this approach is that there is no reason to expect the credit spread to be the same regardless of when the cash flow is expected to be received. Consequently, the credit spread may vary with a bond's term to maturity. In other words, there is a term structure of credit spreads. Generally, credit spreads increase with maturity. This is a typical shape for the term structure of credit spreads. Moreover, the shape of the term structure is not the same for all credit ratings. Typically, the lower the credit rating, the steeper the term structure of credit spreads.

Dealer firms typically estimate the term structure of credit spreads for each credit rating and market sector. Typically, the credit spread increases with maturity. In addition, the shape of the term structure is not the same for all credit ratings. Typically, the lower the credit rating, the steeper the term structure of credit spreads.

When the relevant credit spreads for a given credit rating and market sector are added to the Treasury spot rates, the resulting term structure is used to value the bonds of issuers with that credit rating in that market sector. This term structure is referred to as the *benchmark spot rate curve* or *benchmark zero-coupon rate curve*.

For example, Table 3 reproduces the Treasury spot rate curve in Table 2. Also shown is a hypothetical term structure of credit spreads for a non-Treasury security. The resulting benchmark spot rate curve is in the next-to-the-last column. Like before, it is this spot rate curve

Table 3 Calculation of Arbitrage-Free Value of a Hypothetical 8% 10-Year Non-Treasury Security Using Benchmark Spot Rate Curve

Period	Years	Cash Flow (\$)	Treasury Spot Rate (%)	Credit Spread (%)	Benchmark Spot (%)	Present Value (\$)
1	0.5	4	6.05	0.30	6.35	3.8769
2	1.0	4	6.15	0.33	6.48	3.7529
3	1.5	4	6.21	0.34	6.55	3.6314
4	2.0	4	6.26	0.37	6.63	3.5108
5	2.5	4	6.29	0.42	6.71	3.3916
6	3.0	4	6.37	0.43	6.80	3.2729

18	9.0	4	6.93	0.73	7.66	2.0335
19	9.5	4	7.05	0.77	7.82	1.9301
20	10.0	104	7.20	0.82	<u>8.02</u>	<u>47.3731</u>
					Total	101.763

that is used to value the securities of issuers that have the same credit rating and are in the same market sector. This is done in Table 3 for a hypothetical 8% 10-year issue. The arbitrage-free value is \$101.763. Notice that the theoretical value is less than that for an otherwise comparable Treasury security. The arbitrage-free value for an 8% 10-year Treasury is \$107.0018 (see Table 3).

KEY POINTS

- A bond can be thought of as a portfolio or package of cash flows. Accordingly, the value of a bond is simply the present value of its remaining expected future cash flows.
- There is an inverse relationship between bond prices/required yields.
- The traditional approach to valuation is to discount each cash flow with the same discount rate. The weakness of the traditional

approach is its reliance on using the same discount rate for all of the bond's cash flows.

- The arbitrage-free approach allows each cash flow to be valued as a zero-coupon bond with a discount rate that depends on the shape of the yield curve and when the cash flow is delivered in time.
- The bootstrapping technique is used to derive the discount rates for discounting a bond's cash flows. These discount rates are called spot rates.
- Default-free bonds should trade at prices close to their arbitrage-free values. The process of stripping and reconstituting of Treasury securities ensures that this will occur.

NOTES

1. For a description of these securities, see Fabozzi (2012).

2. There is another method called the “Treasury method,” which treats the coupon interest over the fractional period as simple interest.
3. There is an extensive literature on estimating spot rates or what is known as term structure modeling. See Fabozzi (2002).

Relative Value Analysis of Fixed-Income Products

STEVEN V. MANN, PhD

Professor of Finance, Moore School of Business, University of South Carolina

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Valuation of fixed-income products employs one of two basic methods—discounted cash flows and relative value. Methods using discounted cash flows require several assumptions to be used as inputs but produce a precise valuation result. The tools of relative value analysis are less ambitious. They help us discern differences in value between two similar bonds on a relative basis. Relative value analysis investors make statements such as “Bond X is cheaper than Bond Y.” Relative value tools range in complexity from yield spreads to asset swap spreads and the credit default swap basis.

There are two basic approaches to the valuation of fixed-income products. The *discounted cash flow method* seeks to value a bond given assumptions about cash flows, reference yield curves, risk premiums, and so on. Given these inputs, the bond’s value is determined. Once computed, this value is compared to the prevailing market price and a rich/cheap determination can be made. The alternative method, *relative valuation*, is less ambitious and not surprisingly more popular.

Tools of relative value analysis, when properly interpreted, give the user some clues about how similar bonds are currently valued in the market on a relative basis. This battery of tools allows us to make conjectures such as “Bond X is cheaper than Bond Y.” Yield measures are basic relative value tools. For example, one method

of measuring a risky bond’s relative value is to compute its yield spread relative to a designated benchmark. Discerning relative value is then a matter of comparing the yield spreads of two or more bonds that are otherwise the same. The bond with the largest yield spread is viewed as the cheapest and is considered the best relative value. In this entry, we will introduce yield spread measures utilizing instruments from both the cash and derivatives markets.¹

One common way fixed-income portfolio managers attempt to outperform benchmarks is through security selection. When pursuing a security selection strategy, managers attempt to overweight cheap issues and underweight rich issues to enhance the total rate of return relative to their benchmark. For this to occur, one or

more of the bond's risks must be mispriced. Active security selection to enhance performance leads to the search for effective relative value tools in bond markets.

YIELD SPREADS OVER SWAP AND TREASURY CURVES

As noted, yield spreads are a frequently used tool of relative value analysis. The computation is a simple one. A yield spread is the difference between a risky bond's yield and a benchmark yield holding maturity constant. It is critical to note the yield spread does not have any predictive power on the bondholder's realized return; the yield spread is merely a convenient way to express the price relative to the benchmark.

There are two commonly used benchmarks: the interest rate swap curve and the U.S. Treasury yield curve. A swap is a contract used to transform cash flows from one form to another. In its most basic form, in an interest rate swap two counterparties agree to exchange cash flows at designated future dates for a specified length of time. The fixed-rate payer makes payments that are determined by a fixed rate called a *swap rate*. Correspondingly, the floating-rate payer makes payments based on a reference rate, usually the London Interbank Offered Rate (LIBOR). LIBOR is the interest rate that prime banks in London are willing to pay other prime banks on certificates of deposit denominated in U.S. dollars.

Market participants quote swap rates for swaps across the maturity spectrum. The relationship between the swap rate and the swap's maturity is called the *swap curve*. Since the reference rate for a swap's floating rate payments is usually LIBOR, the swap curve is also referred to as the *LIBOR curve*.

Over time the *swap curve* has supplanted the Treasury yield curve as the benchmark of choice for computing yield spreads. Indeed, in some countries and currencies, the interest rate swap market is more liquid than the market for sovereign debt. It is important to keep in

mind that the swap curve does not represent a set of default-free interest rates. A swap rate is a rate that embodies two risks: (1) the default risk of the counterparty, and (2) liquidity risk.

As noted, in many countries, the swap curve is the benchmark of choice over a country's government securities yield curve. There are several reasons that augur use of the swap curve. First, in order to construct a government bond yield curve that is reflective of the term structure of interest rates, yields on government securities must be available across the entire maturity spectrum. In most government bond markets, however, a limited number of securities are available. For example, the U.S. Treasury issues only six securities with a maturity of two years or more (two, three, five, seven, 10, and 30 years). Conversely, in the swap market, swap rates are quoted on a wide swath of the maturity spectrum.

Second, technical factors introduce some noise into Treasury yields and preclude them from being clear signals of benchmark risk-free interest rates. Treasury securities differ on dimensions other than level of the coupon and maturity. Yields are affected when a note or bond is *cheapest to deliver* into the Treasury note or bond futures contracts. In addition, yields are also affected when the security is "on special" in the repo market. The tax treatment of bonds, especially those trading at a premium or a discount, can affect yields. Swap rates for the most part do not carry this excess baggage and are therefore more reflective of true, albeit risky, interest rates.

Lastly, because of the differences in sovereign credit risk, comparing government yields across countries is tenuous at best. The swap curve, by contrast, reflects roughly the same level of credit risk across countries. Cross-country comparisons are more meaningful.

A spread over the benchmark swap curve is simply the difference between the yield measure in question and the linearly interpolated swap rate at the same maturity. It should be a suitable yield measure such as yield to maturity,

yield to call, or cash flow yield for structured products. Because the swap rate is interpolated, the spread over the benchmark swap curve is often referred to as the *interpolated spread* or the I-spread. Interpolated spreads circumvent the problem of maturity mismatch that affects the level of the spread. This is especially true if the yield curve is steeply sloped.

To find the I-spread, consider a 5.25% coupon bond issued by General Electric (GE) that matures on December 6, 2017. For a settlement date of January 27, 2009, the I-spread was 261.6 basis points. This spread can be interpreted as the compensation the market demanded for the risk differential between the risky bond and the benchmark swap curve.

The yield spreads can also be computed using active or on-the-run Treasuries. On-the-run Treasuries are the most recently issued Treasury securities of a particular maturity. Since the yield curve is not flat, the yield spreads differ depending on the maturity of the on-the-run Treasury. Thus, even if the yield curve remains fixed, the yield spread will change as the bond rolls down the curve. Using the interpolated 8.9-year Treasury yield, suppose the yield spread for the GE bond on January 27, 2009 was 284 basis points. This yield spread can then be compared to similar bonds at the time in order to determine which bond reflects the best relative value.

ASSET SWAPS

An asset swap is a synthetic structure that transforms the nature of the bond's cash flow from one form into another. The structure is created through the combination of a bond position (fixed-rate or floating-rate) with one or more interest rate swaps. Asset swaps are used extensively by financial institutions for asset-liability management. Namely, asset swaps transform the cash flows of long-term fixed-rate assets to floating-rate cash flows, which are in a form more amenable to financial institutions' funding opportunities.

Asset Swap Mechanics

The mechanics of an asset swap are straightforward. An investor, whom we shall refer to as the asset swap buyer, does the following: (1) takes a long position in a fixed-rate coupon bond with a bullet maturity, and (2) simultaneously enters into an off-market interest rate swap with a tenor equal to the bond's remaining term to maturity. An off-market swap is one whose floating rates are determined with a nonzero spread added to the reference rate. Assume that the bond is trading at par. The asset swap buyer enters into an agreement to pay the semiannual coupon payments as the fixed-rate leg in exchange for floating-rate payments at LIBOR plus (or minus) a spread (called the asset swap spread). For simplicity, assume the frequency of the fixed-rate and floating-rate payments are the same. The spread over LIBOR that makes the net present value of the coupon payments (i.e., the fixed-rate leg) and the projected floating-rate payments equal to zero is the *asset swap spread*.² This asset swap spread is used as a measure of relative value regardless of whether the cash flows are actually swapped.

Determining the Asset Swap Spread for a Par Bond

To better understand how all the pieces fit together, let's illustrate how an asset swap spread is calculated. Consider a corporate bond issued by General Electric that matures on December 6, 2017, and pays coupon interest semiannually at an annual rate of 5.25%. Assume a position with a par value of \$1 million. Further assume that this bond sold for par for settlement on December 6, 2008. For ease of exposition, we will evaluate the asset swap on a coupon payment date to abstract some of the details of swaps.

The asset swap spread is determined using the following procedure. First, assume that a \$1 million par value position of the General Electric coupon bond was valued at a price of \$100 for settlement on December 6, 2008. (It actually traded at a large premium at the time.) The

price paid for the bond at settlement is the flat price of \$1,000,000 plus zero accrued interest such that the full price is \$1,000,000 since it is a coupon payment date. Second, assume that a long position in an interest rate swap is established with a notional principal of \$1,000,000. Third, determine the net cash difference at settlement. This amount is simply the difference between the bond's full price and the swap's principal amount plus accrued interest. By construction, this difference is zero in our illustration. Fourth, determine the spread over the reference rate (i.e., LIBOR) required to equate the present value of the swap's floating-rate payments and the present value of the fixed-rate payments (i.e., the bond's cash flows). In our illustration, a swap spread of 221.1 basis points satisfied this condition.

Our illustration is a special case for a bond selling at par, and the accrued interest on both the bond and the swap are equal to zero. The asset swap spread makes the present value of a par swap's floating payments equal the bond's payments to maturity. This is true because the net cash at settlement is equal to zero.

Par versus Market Structures

Market participants use two types of fixed-floating asset swap structures—par and market. The par structure is the most prevalent. When utilizing a *par structure*, the notional amount of the interest rate swap is equal to the bond's maturity value. The price of the bond acquired by the asset swap buyer is par regardless of its market price.³ If the bond is trading at a discount, the asset swap seller receives more for the bond than it is worth and garners an upfront "profit." Alternatively, if the bond is trading at a premium, the asset swap seller receives less for the bond than it is worth and suffers an upfront "loss." At the initiation of the asset swap, the present value of the net cash flows of both parties is zero, so any upfront profit or loss is illusory because the spread adjusts. The asset swap seller "gives up" the premium over par

at inception and in return pays a lower spread on the floating-rate cash flows. For bonds trading at a discount, the asset swap seller pays a higher spread on the floating-rate cash flows as recompense for capturing the discount at settlement.

An asset swap with a par structure is two separate transactions: (1) The asset swap buyer pays par to the asset swap seller for a bond and (2) an off-market swap. Accordingly, after the asset swap's cash flows are established, the bond's credit performance has no impact on the interest rate swap. If the bond were to default, the asset swap buyer no longer receives coupon payments or the maturity payment. The asset swap buyer's obligations imposed by the swap continue on as before until it matures or can be closed out at market value.

An alternative structure for an asset swap is called a market structure. This method differs from a par structure in four respects. First, the bond is purchased at its prevailing market price rather than at par. Second, the notional principal of the off-market swap floating-rate payments is scaled by the bond's full price. Third, at the end of the transaction's life, the asset swap buyer pays par to the asset swap seller and receives the original full price of the bond. Lastly, note also that the counterparty risk exposure is allocated differently in the two asset swap structures. If the bond in question trades at a premium, the asset swap seller bears more of the counterparty risk. Conversely, in a market structure for the same premium bond, the counterparty risk is tilted toward the asset swap buyer due to the net payment of the bond's premium at the end of the transaction. Correspondingly, if the bond in question trades at a discount, the tilt of the counterparty risk exposure is reversed for both structures.

Determining the Asset Swap Spread in the General Case

Let's introduce some real-world complications. First, we consider an asset swap with a

settlement date that falls between two coupon payment dates. Once this circumstance is considered, both the coupon-paying bond and swap will have nonzero accrued interest. Suppose an asset swap with a par structure has a settlement day that falls between the two semiannual coupon payment dates. By market convention, the asset swap buyer pays par for the bond and does not directly pay accrued interest. The asset swap buyer receives the full coupon payment at the next payment date and pays the full coupon payment as required on the fixed-rate side of the swap. The floating-rate swap payment from the asset swap seller is treated somewhat differently. Floating-rate payments are usually more frequent than fixed-rate payments (quarterly versus semiannually) and almost always use a different day count convention. The floating-rate payment is adjusted accordingly.

As an illustration, consider a 4.125% coupon bond issued by Wal-Mart that matured on February 15, 2011. This bond delivered coupon payments semiannually. Suppose an asset swap buyer took a long position in this bond that was trading at a flat price of 103.764. We will sketch the procedure for calculating the asset swap spread if it had a trade settlement date of June 23, 2008. The notional principal is set to the default of \$1 million. The asset swap spread that equates the present value of the cash flows was 75.7 basis points. As a result, the floating-rate swap payments would have been calculated with a rate of 3-month LIBOR plus 75.7 basis points. The asset swap buyer's swap payments would have been simply the five semiannual coupon payments of \$20,625 and \$1,000,000 on the maturity date of February 15, 2011. The asset swap seller's floating-rate swap payments would have depended on the value of 3-month LIBOR on each payment date. As noted, the first floating-rate payment of \$2,835.04 reflects the accrual from the settlement date on January 28, 2009, to the first payment date of February 15, 2009, using an actual/360 day count convention.

Uses of Asset Swaps

The primary reason for using an asset swap is to acquire some exposure to risks of a fixed rate while neutralizing the interest rate risk. For example, financial institutions typically fund on a floating-rate basis and unless they have a view on interest rates, management wants to invest in floating-rate assets. Financial institutions are active participants in the asset swap market by buying fixed-rate bonds and transforming the cash flow from those bonds into floating payments, which provide a better match against their liability structure. An active asset swap market tends to eliminate pricing discrepancies between fixed-rate and floating-rate products.

Asset swap spreads are often used as an indicator of relative value. If a fixed-income investor is considering five fixed-rate bonds of similar maturity and risk for inclusion in a portfolio and wants to assess their relative value, the investor would simply find the highest asset swap spreads, which represent the best relative value.

In practice, however, asset swaps are typically employed as a relative value detector in the following manner. After choosing portfolio duration (and perhaps key rate durations to control shaping risk) and after choosing a credit mix (or perhaps an average credit rating), find the constrained portfolio that produces the highest asset swap spread. This portfolio presumably represents the best relative value for a given duration target and credit target—with or without distributional constraints on durations and credit ratings.

A Miscellany of Asset Swaps

There are a handful of variations on the standard asset swap structure discussed to this point. A forward start asset swap involves taking a long position in a risky bond on a forward settlement date in combination with an interest rate swap whose asset swap spread is established today. This transaction allows an investor to gain an exposure to a risky product in the future at a known price today. Investors bear

no exposure to credit risk until the forward settlement date because the asset swap terminates if the bond defaults prior to this date.

A cross-currency asset swap is a combination of a long position in a risky bond whose cash flows are denominated in a different currency and an off-market interest rate swap. The swap transforms the fixed-rate coupon payments into floating-rate cash flows in the investor's home currency. An exchange of principal occurs at the end of the swap's life as is common with currency swaps. Moreover, the swap's cash flows are converted using a predetermined exchange rate. This asset swap variation would allow, say, a U.S. investor to take an exposure to a yen-denominated corporate bond while simultaneously mitigating the interest rate and currency risks.

Investors often use asset swaps in convertible bond arbitrage. Convertibles are ideal securities for "arbitrage" because the convertible itself, namely the underlying stock and the embedded derivatives, are traded along predictable ratios and any discrepancy or mispricing would give rise to arbitrage opportunities for hedge fund managers to exploit. The valuation of convertible bonds is driven by four primary factors: (1) interest rates, (2) credit spreads, (3) stock prices, and (4) volatility of stock prices. Convertible bond arbitrage involves taking a leveraged position (usually long) in the convertible bond to gain exposure to a mispriced factor while simultaneously hedging interest rates and small changes in stock prices.

Callable asset swaps are used to strip out equity and credit components with a structure that allows the investor to cancel the off-market swap on any call date. This ability to terminate the swap is accomplished through the purchase of Bermudan receiver swaptions.

CREDIT DEFAULT SWAPS

Credit default swaps (CDS) are contracts that enable the transfer of credit risk between the two

counterparties to the trade. CDS resemble insurance policies.⁴ Taking long/short CDS positions is referred to as buying/selling "protection." The protection buyer pays the protection seller a periodic payment (premium) for protection against a credit event experienced by a reference asset or entity. Simply put, sellers of protection are taking on credit risk for a fee while protection buyers are paying to reduce their credit risk exposure. A reference asset could refer to a single asset, and this is termed a single-name credit default swap. Alternatively, if the reference asset is a group of assets, it is referred to as a basket credit default swap. A reference entity could be a corporation or government entity (sovereign or municipal).

The payout of credit default swaps is contingent on the occurrence of a *credit event*. Definitions of credit events are published by the ISDA, the so-called "1999 Definitions." The 1999 Definitions list eight different credit events, which include: (1) bankruptcy, (2) credit event upon merger, (3) cross acceleration, (4) cross default, (5) downgrade, (6) failure to pay, (7) repudiation/moratorium, and (8) restructuring. The most controversial credit event is a restructuring. A restructuring refers to an alteration of the debt obligation's original terms in an effort to make the obligation less onerous to the borrower. Among the terms that may be offered: (1) reduction in the stated rate of interest, (2) principal reduction, (3) principal payment rescheduling or interest payment postponement, or (4) a change in the seniority level of the obligation. The inclusion of restructuring as a trigger for a credit event is desired by protection buyers because they insist it is part of their essential credit protection. Protection sellers counter that the restructuring provision is triggered by routine modifications to the debt. In April 2001, the ISDA issued the so-called "Supplement Definition" that indicates the conditions needed to qualify for a restructuring: (1) The reference obligation must have at least four bondholders, and (2) at least two-thirds of the bondholders must consent to the restructuring.

The market for single-name credit default swaps is an over-the-counter interdealer market. For credit default swaps on corporate or sovereign debt, the contract specifications are largely standardized. For example, the tenor is usually five years. Certain dealers are also willing to create customized contracts better suited to the counterparty’s risk exposure. A protection buyer makes payments (typically quarterly) that are fixed by contract until a credit event is triggered or maturity, whichever is earlier. The formula for calculating the protection buyer’s quarterly is given by the expression

$$\begin{aligned} \text{quarterly payment} &= \text{CDS spread} \\ &\times \text{notional principal} \\ &\times (\text{days in period})/360 \end{aligned}$$

Figure 1 presents these payments. If a credit event does not occur during the tenor of the CDS, the protection buyer’s fixed payments are the only payments. At inception, there is no exchange of principal between the buyer and the seller. If a credit event is triggered, there is an exchange between the protection buyer and protection seller. The protection buyer makes accrued payments up until the credit event date and then stops making quarterly payments.

What both parties must do when there is a credit event depends on the settlement terms of the CDS. The settlement terms can specify either physical settlement or cash settlement. If the CDS specifies physical delivery, the protection buyer delivers the reference obligation to the protection seller in return for the cash payment. Figure 2 illustrates this scenario. If the credit event is triggered, the seller’s pay-

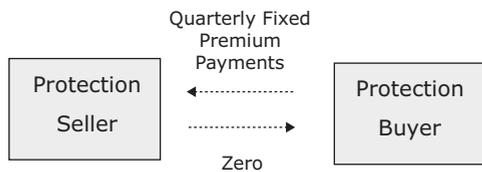

Figure 1 Premium Payments for a CDS Assuming no Credit Event

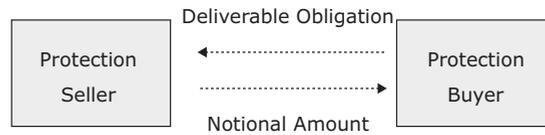

Figure 2 The Exchange if a Credit Event Occurs

ment may be a prespecified amount or it may reflect the reference obligation’s value decline. When the payment is fixed, it is based on a notional principal amount. Conversely, when the payment is based on the reference obligation’s value decline, it is usually computed using pricing information obtained by polling several CDS dealers.

Usually there is more than one obligation of the reference entity from which the protection buyer can choose. The set of all obligations that are permitted for physical delivery is called the deliverable obligations. Any obligation meeting the stated criteria (coupon, maturity, etc.) is part of this basket. Naturally, the protection buyer will choose among the deliverable obligations the one that is cheapest to deliver.

CDS are structured to replicate the experience of a default in the cash market. If a credit event occurs, the deliverable obligation should trade at a deep discount to par.

The seller’s net loss will be the difference between par and the deliverable obligation’s recovery value. Note that the CDS is a pure play in the deliverable obligation’s credit risk. A long position in the reference instrument exposes the investor to other risks.

As an illustration, consider a CDS with a reference asset being a Citigroup 6.5% coupon bond that matured on January 18, 2011. The notional principal for this contract was \$10 million. Suppose the following information was available:

Reference Entity/Asset	Citigroup 6.5% 1/18/2011
Tenor	5 years
Effective date	7/3/08
Maturity date	9/20/13
Payment frequency	Quarterly

The first coupon payment date was September 22, 2008. Suppose the deal spread was 143.5 basis points. Presented in the following table are the first four quarterly payments that the protection buyer made to the seller.

Date	Cash flow (\$)
9/22/08	\$32,287.50
12/22/08	\$36,273.61
3/20/09	\$35,077.78
6/22/09	\$37,469.44

There were 81 actual days of accrual from the effective date of 7/3/08 to the first coupon date of 9/22/08, so inserting this number along with the notional principal of \$10 million and a spread of 143.5 basis points (in decimal) gives the first quarterly payment of

$$\$32,287.50 = 0.01435 \times \$10 \text{ million} \times (81/360)$$

The remainder of the quarterly payments are computed in the same fashion. Note that while the CDS spread remains fixed, the payments will vary somewhat due to the varying number of days between coupon payment dates.

Credit Default Swap Basis

A CDS is, under certain simplifying assumptions, equivalent to a long position in an asset-swapped fixed-rate bond financed with a repurchase (repo) agreement. Accordingly, it is critical to address the linkage between asset swap spreads, CDS spreads, and credit spreads.

Practitioners access relative value by comparing CDS spreads and asset-swap spread levels. In fact, the difference between the CDS premium and the asset swap spread is referred to as the *credit default swap basis* (CDS basis).⁵ Practitioners also look at differences between CDS spreads and either the I-spread or the zero-volatility spread (Z-spread). A nonzero basis signals opportunities for investors. If the basis is negative (i.e., the CDS spread is less than the asset swap spread), this suggests that the investor buy the bond in the cash market and buy protection via a CDS. Conversely, if the basis

is positive (i.e., the CDS spread is greater than the asset swap spread), this suggests that the investor sell the bond in the cash market and sell protection via a CDS.

KEY POINTS

- There are two approaches to the valuation of fixed-income products: discounted cash flow and relative value.
- The relative value method can provide information about how similar bonds are priced on a relative basis.
- A yield spread is the difference between a risky bond's yield and a benchmark yield holding maturity constant.
- Two commonly used benchmark yield curves are the swap curve and the U.S. Treasury curve.
- An asset swap is a synthetic structure that transforms the nature of cash flows from one form into another.
- An asset swap spread is used as an indicator of relative value and is the spread over the reference rate that equates the value of the floating rate cash flows and the bond's cash flows.
- The credit default swap (CDS) basis is the difference between the CDS premium and the asset swap spread.
- A nonzero CDS basis signals opportunities for investors.

NOTES

1. For a further discussion of relative value tools, see Fabozzi and Mann (2010) and Grieves and Mann (2010).
2. For simplicity, we are ignoring any nonzero net payments at the beginning and end of the swap's life. These elements will be introduced shortly.
3. When nonpar bonds are purchased as part of an asset swap structure, tax and accounting rules create incentives to buy and sell premium/discount bonds at par through an asset swap structure.

4. More on the mechanics of CSD can be found in Anson, Fabozzi, Choudhry, and Chen (2004).
5. For a further discussion of the CDS spread, see Choudhry (2006).

Abstract: The complication in valuing bonds with embedded options and option-type derivatives is that cash flows depend on interest rates in the future. Academicians and practitioners have attempted to capture this interest rate uncertainty through various models, often designed as one- or two-factor processes. These models attempt to capture the stochastic behavior of rates. In practice, these elegant mathematical models must be implemented numerically in order to be useful. One such model is a single factor model that assumes a stationary variance, or volatility.

An often-used framework for the valuation of interest rate instruments with embedded options and interest rate option-type derivatives is the lattice framework. Effectively, the lattice specifies the distribution of short-term interest rates over time. The lattice holds all the information required to perform the valuation of certain option-like interest rate products. First, the lattice is used to generate the cash flows across the life of the security. Next, the interest rates on the lattice are used to compute the present value of those cash flows.

There are several interest rate models that have been used in practice to construct an *interest rate lattice*. In each case, interest rates can realize one of several possible levels when we move from one period to the next. A lattice model that

allows only two rates in the next period is called a binomial model. A lattice model that allows three possible rates in the next period is called a trinomial model. There are even more complex models that allow more than three possible rates in the next period.

Regardless of the underlying assumptions, each model shares a common restriction. In order to be “arbitrage-free,” the interest rate tree generated must produce a value for an on-the-run optionless bond that is consistent with the current par *yield curve*. In effect, the value generated by the model must be equal to the observed market price for the optionless instrument. Under these conditions the model is said to be “arbitrage free.” A lattice that produces an arbitrage-free valuation is said to be “fair.” The

lattice is used for valuation only when it has been calibrated to be fair. More on calibration below.

In this entry we will demonstrate how a lattice is used to value an option-free bond. The model is also used to value bonds with embedded options, floating-rate securities with option-type derivatives, bond options, and swaptions.¹

THE INTEREST RATE LATTICE

In our illustration, we represent the lattice as a binomial tree, the simplest lattice form. Figure 1 provides an example of a *binomial interest rate tree*, which consists of a number of “nodes” and “legs.” Each leg represents a one-year interval over time. A simplifying assumption of one-year intervals is made to illustrate the key principles. The methodology is the same for smaller time periods. In fact, in practice the selection of the length of the time period is critical, but we need not be concerned with this nuance here.

The distribution of future interest rates is represented on the tree by the nodes at each point in time. Each node is labeled as “N” and has

a subscript, a combination of L’s and H’s. The subscript indicates whether the node is lower or higher on the tree, respectively, relative to the other nodes. Thus, node N_{HH} is reached when the 1-year rate realized in the first year is the higher of the two rates for that period, then the highest of the rates in the second year.

The root of the tree is N , the only point in time at which we know the interest rate with certainty. The 1-year rate today (that is, at N) is the current 1-year spot rate, which we denote by r_0 .

We must make an assumption concerning the probability of reaching one rate at a point in time. For ease of illustration, we have assumed that rates at any point in time have the same probability of occurring. In other words, the probability is 50% on each leg.

The interest rate model we will use to construct the binomial tree assumes that the 1-year rate evolves over time based on a lognormal random walk with a known (stationary) volatility. Technically, the tree represents a *one-factor model*. Under the distributional assumption, the relationship between any two adjacent rates at a point in time is calculated via the following equation:

$$r_{1,H} = r_{1,L} e^{2\sigma\sqrt{t}}$$

where σ is the assumed volatility of the 1-year rate, t is the length of the time period in years, and e is the base of the natural logarithm. Since we assume a 1-year interval, that is, $t = 1$, we can disregard the calculation of the square root of t in the exponent.

For example, suppose that $r_{1,L}$ is 4.4448% and σ is 10% per year, then:

$$\begin{aligned} r_{1,H} &= 4.4448\%(e^{2 \times 0.10}) = 4.4448\%(1.2214) \\ &= 5.4289\% \end{aligned}$$

In the second year, there are three possible values for the 1-year rate. The relationship between $r_{2,LL}$ and the other two 1-year rates is as follows:

$$r_{2,HH} = r_{2,LL}(e^{4\sigma}) \quad \text{and} \quad r_{2,HL} = r_{2,LL}(e^{2\sigma})$$

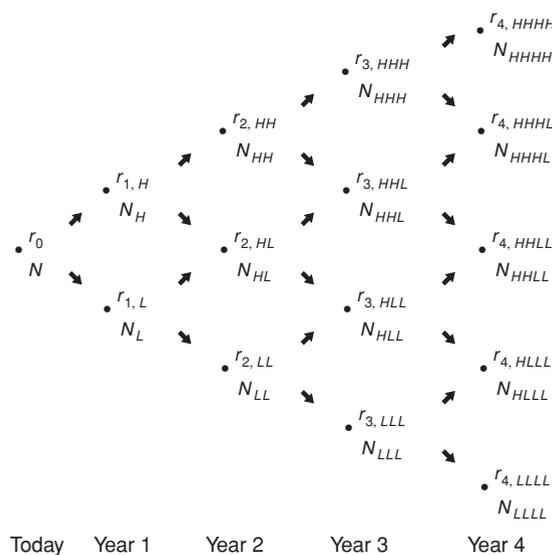

Figure 1 Four-Year Binomial Interest Rate Tree

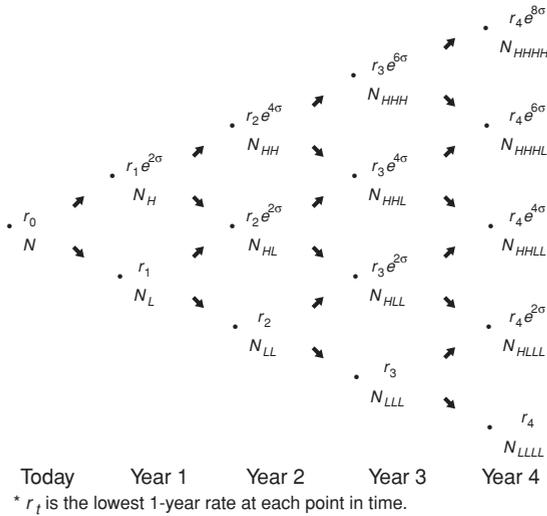

Figure 2 Four-Year Binomial Interest Rate Tree with 1-Year Rates*

So, for example, if $r_{2,LL}$ is 4.6958%, and assuming once again that σ is 10%, then

$$r_{2,HH} = 4.6958\%(e^{4 \times 0.10}) = 7.0053\%$$

and

$$r_{2,HL} = 4.6958\%(e^{2 \times 0.10}) = 5.7354\%$$

This relationship between rates holds for each point in time. Figure 2 shows the interest rate tree using this notation.

Determining the Value at a Node

In general, to get a security's value at a node we follow the fundamental rule for valuation: The value is the present value of the expected cash flows. The appropriate discount rate to use for cash flows one year forward is the 1-year rate at the node where we are computing the value. Now there are two present values in this case: the present value of the cash flows in the state where the 1-year rate is the higher rate, and one where it is the lower rate state. We have assumed that the probability of both outcomes is equal. Figure 3 provides an illustration for a node assuming that the 1-year rate is r^* at the node where the valuation is sought and letting:

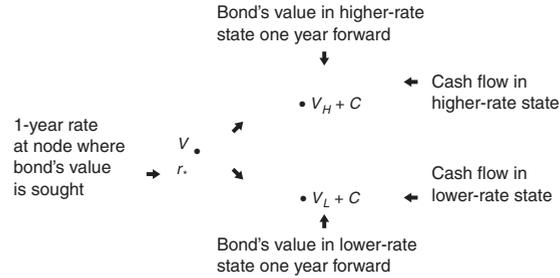

Figure 3 Calculating a Value at a Node

V_H = the bond's value for the higher 1-year rate state

V_L = the bond's value for the lower 1-year rate state

C = coupon payment

From where do the future values come? Effectively, the value at any node depends on the future cash flows. The future cash flows include (1) the coupon payment one year from now and (2) the bond's value one year from now, both of which may be uncertain. Starting the process from the last year in the tree and working backwards to get the final valuation resolves the uncertainty. At maturity, the instrument's value is known with certainty—par. The final coupon payment can be determined from the coupon rate, or from prevailing rates to which it is indexed. Working back through the tree, we realize that the value at each node is quickly calculated. This process of working backward is often referred to as *recursive valuation*.

Using our notation, the cash flow at a node is either:

- $V_H + C$ for the higher 1-year rate
- $V_L + C$ for the lower 1-year rate

The present value of these two cash flows using the 1-year rate at the node, r^* , is:

$$\frac{V_H + C}{(1 + r^*)} = \text{present value for higher 1-year rate}$$

$$\frac{V_L + C}{(1 + r^*)} = \text{present value for lower 1-year rate}$$

Then, the value of the bond at the node is found as follows:

$$\text{Value at a node} = \frac{1}{2} \left[\frac{V_H + C}{(1 + r^*)} + \frac{V_L + C}{(1 + r^*)} \right]$$

CALIBRATING THE LATTICE

We noted above the importance of the no-arbitrage condition that governs the construction of the lattice. To assure this condition holds, the lattice must be calibrated to the current par yield curve, a process we demonstrate here. Ultimately, the lattice must price optionless par bonds at par.

Assume the on-the-run par yield curve for a hypothetical issuer as it appears in Table 1. The current 1-year rate is known, 3.50%. Hence, the next step is to find the appropriate 1-year rates one year forward. As before, we assume that volatility, σ , is 10% and construct a 2-year tree using the 2-year bond with a coupon rate of 4.2%, the par rate for a 2-year security.

Figure 4 shows a more detailed binomial tree with the cash flow shown at each node. The root rate for the tree, r_0 , is simply the current 1-year rate, 3.5%. At the beginning of Year 2 there are two possible 1-year rates, the higher rate and the lower rate. We already know the relationship between the two. A rate of 4.75% at N_L has been arbitrarily chosen as a starting point. An iterative process determines the proper rate (that is, trial and error). The steps are described and illustrated below. Again, the goal is a rate that, when applied in the tree, provides a value of par for the 2-year, 4.2% bond.

Step 1: Select a value for r_1 . Recall that r_1 is the lower 1-year rate. In this first trial, we arbitrarily selected a value of 4.75%.

Table 1 Issuer Par Yield Curve

Maturity	Par Rate	Market Price
1 year	3.50%	100
2 years	4.20%	100
3 years	4.70%	100
4 years	5.20%	100

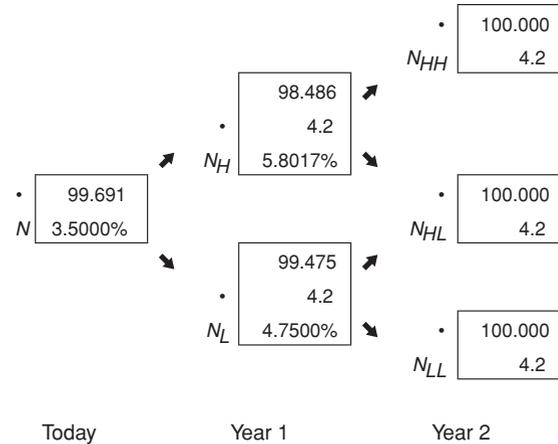

Figure 4 The 1-Year Rates for Year 1 Using the 2-Year 4.2% On-the-Run Issue: First Trial

Step 2: Determine the corresponding value for the higher 1-year rate. As explained earlier, this rate is related to the lower 1-year rate as follows: $r_1 e^{2\sigma}$. Since r_1 is 4.75%, the higher 1-year rate is 5.8017% ($= 4.75\% e^{2 \times 0.10}$). This value is reported in Figure 4 at node N_H .

Step 3: Compute the bond's value one year from now as follows:

- Determine the bond's value two years from now. In our example, this is simple. Since we are using a 2-year bond, the bond's value is its maturity value (\$100) plus its final coupon payment (\$4.2). Thus, it is \$104.2.
- Calculate V_H . Cash flows are known. The appropriate discount rate is the higher 1-year rate, 5.8017% in our example. The present value is \$98.486 ($= \$104.2 / 1.058017$).
- Calculate V_L . Again, cash flows are known—the same as those in Step 3b. The discount rate assumed for the lower 1-year rate is 4.75%. The present value is \$99.475 ($= \$104.2 / 1.0475$).

Step 4: Calculate V .

- Add the coupon to both V_H and V_L to obtain the values at N_H and N_L , respectively. In our example we have \$102.686 for the higher rate and \$103.675 for the lower rate.

b. Calculate V . The 1-year rate is 3.50%.
 (Note: At this point in the valuation, r^* is the root rate, 3.50%. Therefore, $\$99.691 = 1/2(\$99.214 + \$100.169)$.)

Step 5: Compare the value in Step 4 to the bond's market value. If the two values are the same, then the r_1 used in this trial is the one we seek. If, instead, the value found in Step 4 is not equal to the market value of the bond, then r_1 in this trial is not the 1-year rate that is consistent with the current yield curve. In this case, the five steps are repeated with a different value for r_1 .

When r_1 is 4.75%, a value of \$99.691 results in Step 4, which is less than the observed market price of \$100. Therefore, 4.75% is too large and the five steps must be repeated trying a lower rate for r_1 .

Let's jump right to the correct rate for r_1 in this example and rework Steps 1 through 5. This occurs when r_1 is 4.4448%. The corresponding binomial tree is shown in Figure 5. The value at the root is equal to the market value of the 2-year issue (par).

We can "grow" this tree for one more year by determining r_2 . Now we will use the 3-year on-the-run issue, the 4.7% coupon bond, to get r_2 . The same five steps are used in an iterative

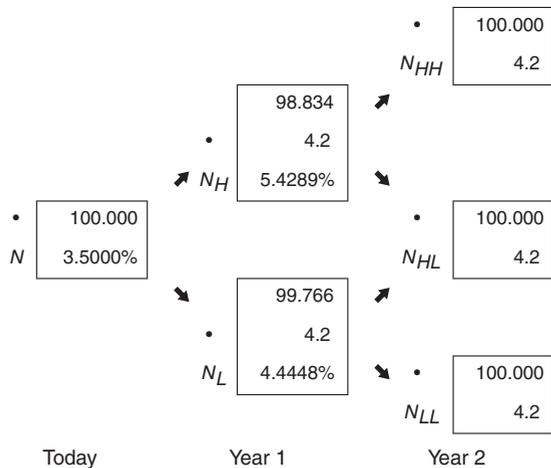

Figure 5 The 1-Year Rates for Year 1 Using the 2-Year 4.2% On-the-Run Issue

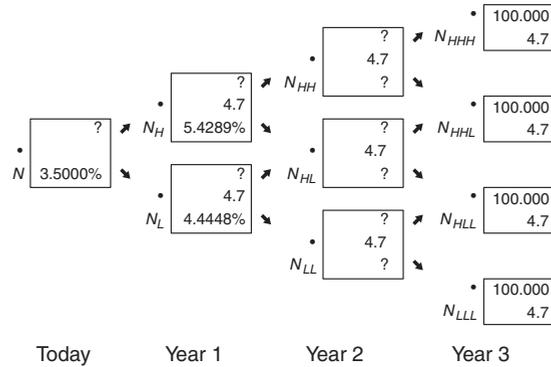

Figure 6 Information for Deriving the 1-Year Rates for Year 2 Using the 3-Year 4.7% On-the-Run Issue

process to find the 1-year rates in the tree two years from now. Our objective is now to find the value of r_2 that will produce a bond value of \$100. Note that the two rates one year from now of 4.4448% (the lower rate) and 5.4289% (the higher rate) do not change. These are the fair rates for the tree one year forward.

The problem is illustrated in Figure 6. The cash flows from the 3-year, 4.7% bond are in place. All we need to perform a valuation are the rates at the start of Year 3. In effect, we need to find r_2 such that the bond prices at par. Again, an arbitrary starting point is selected, and an iterative process produces the correct rate.

The completed version of Figure 6 is found in Figure 7. The value of r_2 , or equivalently

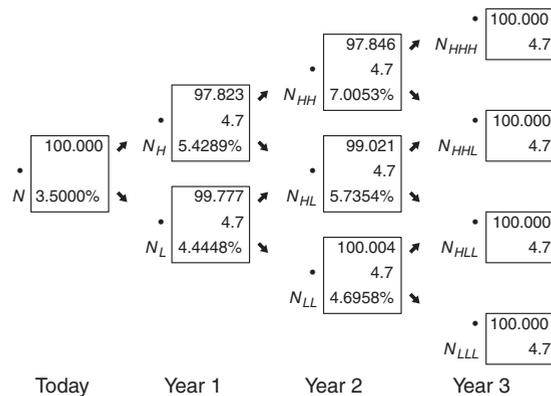

Figure 7 The 1-Year Rates for Year 2 Using the 3-Year 4.7% On-the-Run Issue

$r_{2,LL}$, which will produce the desired result is 4.6958%. The corresponding rates $r_{2,HL}$ and $r_{2,HH}$ would be 5.7354% and 7.0053%, respectively. To verify that these are the correct 1-year rates two years from now, work backwards from the four nodes at the right of the tree in Figure 7. For example, the value in the box at N_{HH} is found by taking the value of \$104.7 at the two nodes to its right and discounting at 7.0053%. The value is \$97.846. Similarly, the value in the box at N_{HL} is found by discounting \$104.70 by 5.7354% and at N_{LL} by discounting at 4.6958%.

USING THE LATTICE FOR VALUATION

To illustrate how to use the lattice for valuation purposes, consider a 6.5% option-free bond with four years remaining to maturity. Since this bond is option-free, it is not necessary to use the lattice model to value it. All that is necessary to obtain an arbitrage-free value for this bond is to discount the cash flows using the spot rates obtained from bootstrapping the yield curve shown in Table 1. (All calculations are highly sensitive to the number of decimal places chosen.) The spot rates are as follows:

1-year	3.5000%
2-year	4.2147%
3-year	4.7345%
4-year	5.2707%

Discounting the 6.5% 4-year option-free bond with a par value of \$100 at the above spot rates would give a bond value of \$104.643.

Figure 8 contains the fair tree for a four-year valuation. Figure 9 shows the various values in the discounting process using the lattice in Figure 8. The root of the tree shows the bond value of \$104.643, the same value found by discounting at the spot rate. This demonstrates that the lattice model is consistent with the valuation of an option-free bond when using spot rates.

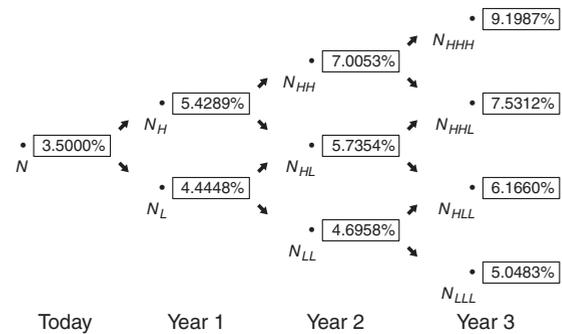

Figure 8 Binomial Interest Rate Tree for Valuing up to a 4-Year Bond for Issuer (10% Volatility Assumed)

The lesson here can be applied to more complex instruments, those with option features that require the lattice-based process for proper valuation and derivatives such as swaptions. Regardless of the security or derivative to be valued, the generation of the lattice follows the same no-arbitrage principles outlined here. Subsequently, cash flows are determined at each node, the recursive valuation process undertaken to arrive at fair values. Hence, a single lattice and a valuation process prove to be robust means for obtaining fair values for a wide variety of fixed income instruments.

KEY POINTS

- The complication in valuing bonds with embedded options and option-type derivatives is that cash flows depend on interest rates in the future.
- In practice, several interest rate models have been employed to construct an interest rate lattice. In each case, interest rates can realize one of several possible levels when we move from one period to the next. There are binomial lattices (two possible rates in the next period), trinomial lattices (three possible rates in the next period), and even more complex models that allow more than three possible rates in the next period.

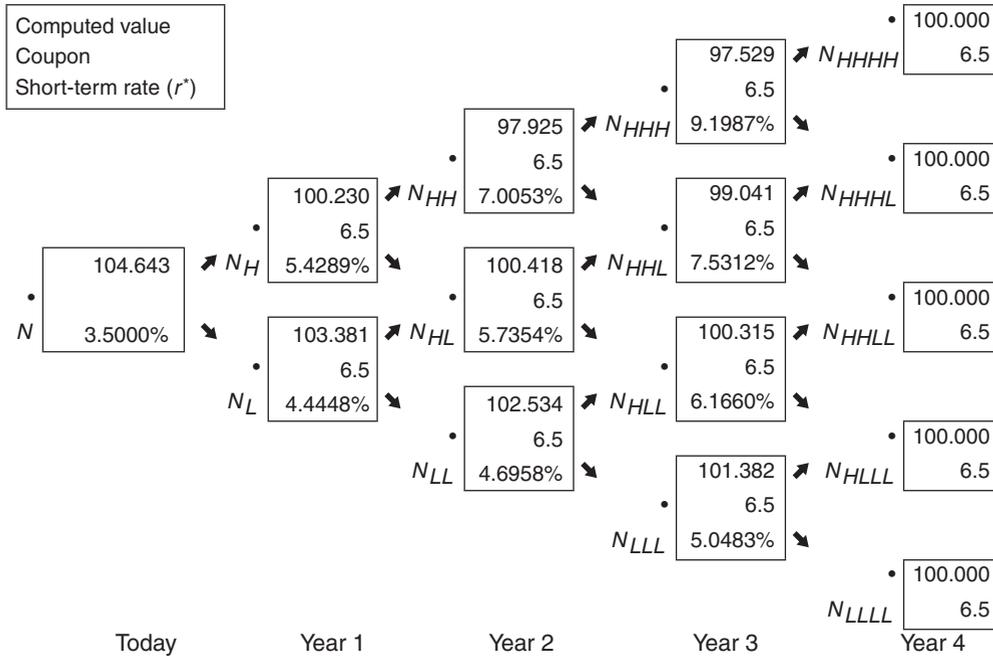

Figure 9 Valuing an Option-Free Bond with Four Years to Maturity and a Coupon Rate of 6.5% (10% Volatility Assumed)

- Several models have been developed to value bonds with embedded options and option-type interest rate derivatives, the most common model being a one-factor model.
- The lattice framework uses an arbitrage-free interest rate lattice or tree to generate the cash flows over the life of the financial instrument and then to determine the present value of the cash flow. The present value of the cash flow is then the fair value of the financial instrument.
- The lattice must be constructed so as to be consistent with (that is, calibrated to) the observed market value of an on-the-run option-free issue.

NOTE

1. For an extensive discussion of the application to the valuation of embedded options in bonds see Kalotay, Williams, and Fabozzi (1993), and for the application to interest rate swaptions see Fabozzi and Buetow (2000).

Abstract: In principle, the valuation of a financial instrument is straightforward: It is the present value of the expected cash flow. For fixed income securities, the expected cash flow, ignoring the possibility of default, is the periodic interest payments and the maturity value. The interest rates used to discount the expected cash flows are obtained from an appropriate benchmark spot rate curve. When a fixed-rate or floating-rate bond has an interest-sensitive embedded option such as a call option, put option, or a cap in the case of a floater, the expected cash flow will be dependent on future interest rates. To value fixed income securities with embedded options, the lattice framework is the standard tool in practice. The same lattice-based framework is also used to value interest-sensitive derivatives such as options, caps, and floors.

We will demonstrate in this entry how the *lattice* framework provides a robust means for valuing fixed-rate and floating-rate bonds and interest rate derivatives. In addition, we extend the application of the interest rate tree to the calculation of the option-adjusted spread, as well as the effective duration and convexity of a fixed income instrument. The model described below was first introduced by Kalotay, Williams, and Fabozzi (1993).

FIXED-COUPON BONDS WITH EMBEDDED OPTIONS

The valuation of bonds with embedded options proceeds in the same fashion as in the case of an *option-free bond*. However, the added complexity of an embedded option requires an adjustment to the cash flows on the tree depending on the structure of the option. A decision on whether to call or put must be made at nodes

on the tree where the option is eligible for exercise. Examples for both *callable* and *puttable* bonds follow. The analysis can be extended to cases where there are several embedded options such as a callable bond with an accelerated sinking fund provision.

Valuing a Callable Bond

In the case of a call option, the call will be made when the present value (PV) of the future cash flows is greater than the call price at the node where the decision to exercise is being made. Effectively, the following calculation is made:

$$V_t = \text{Min}[\text{Call Price}, \text{PV}(\text{Future Cash Flows})]$$

where V_t represents the PV of future cash flows at the node. This operation is performed at each node where the bond is eligible for call.

For example, consider a 6.5% bond with four years remaining to maturity that is callable in one year at \$100. We will value this bond, as well as the other instruments in this entry, using a binomial tree. The on-the-run yield curve for the issuer used to construct the tree is given in Table 1. The methodology for constructing the *binomial interest rate tree* from the yield curve is not discussed here but is explained in Entry 16. Application of the methodology results in the binomial interest rate tree in Figure 1. In constructing the binomial tree in Figure 1, it is assumed that interest rate volatility is 10% and that cash flows occur at the end of the year. This binomial tree will be used throughout this entry.

Figure 2 shows two values are now present at each node of the binomial tree. The discounting process is used to calculate the first of the two values at each node. The second value is the value based on whether the issue will be called. To simplify the analysis, it is assumed that the

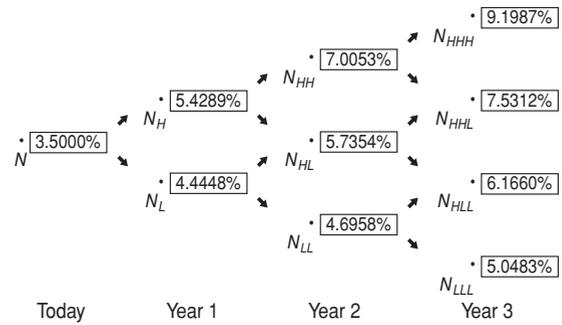

Figure 1 Binomial Interest Rate Tree for Valuing up to a Four-Year Bond for Issuer (10% Volatility Assumed)

issuer calls the issue if the PV of future cash flows exceeds the call price. This second value is incorporated into the subsequent calculations.

In Figure 3 certain nodes from Figure 2 are highlighted. Panel (a) of the figure shows nodes where the issue is not called (based on the simple call rule used in the illustration) in year 2 and year 3. The values reported in this case are the same as in the valuation of an option-free bond. Panel (b) of the figure shows some nodes where the issue is called in year 2 and year 3. Notice how the methodology changes the cash flows. In year 3, for example, at node N_{HLL} the *recursive valuation process* produces a PV of 100.315.¹ However, given the call rule, this issue would be called. Therefore, 100 is shown as the second value at the node and it is this value that is then used as the valuation process continues. Taking the process to its end, the value for this callable bond is 102.899.

The value of the call option is computed as the difference between the value of an optionless bond and the value of a callable bond. In our illustration, the value of the option-free bond can be shown to be 104.643. The value of the callable bond is 102.899. Hence, the value of the call option is 1.744 (=104.634 – 102.899).

Table 1 Issuer Par Yield Curve

Maturity	Par Rate	Market Price
1 year	3.50%	100
2 years	4.20%	100
3 years	4.70%	100
4 years	5.20%	100

Valuing a Puttable Bond

A puttable bond is one in which the bondholder has the right to force the issuer to pay off the

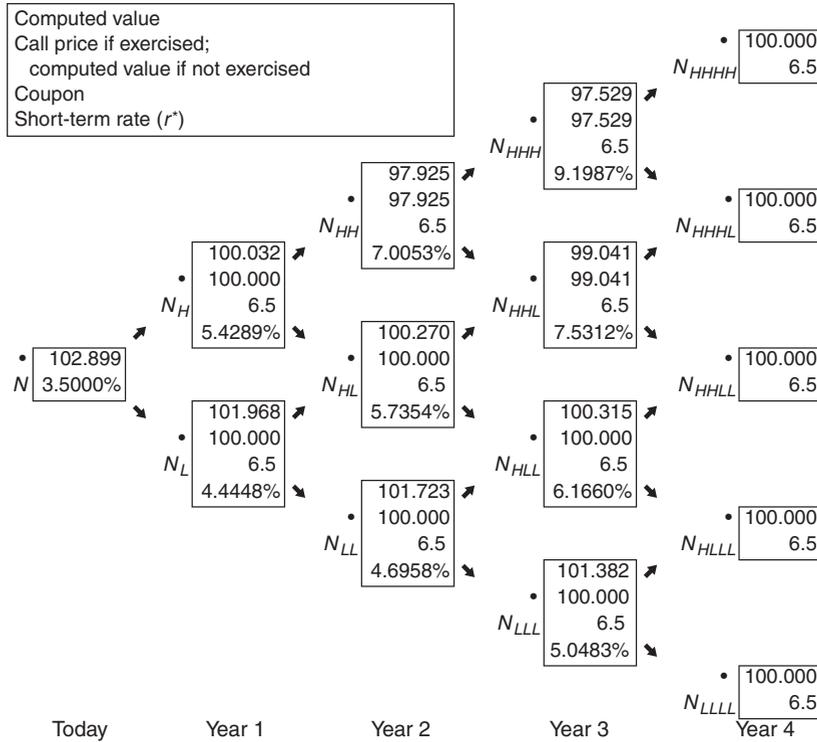

Figure 2 Valuing a Callable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Callable after the First Year at 100 (10% Volatility Assumed)

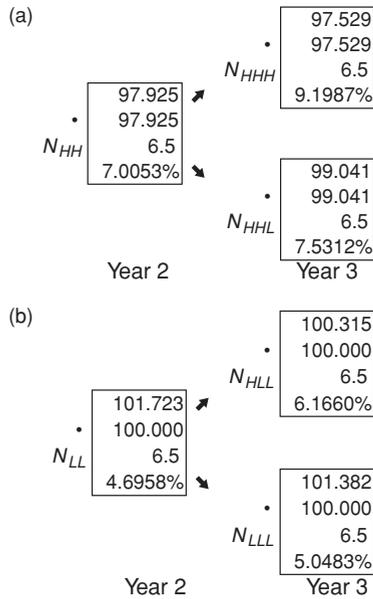

Figure 3 Highlighting Nodes in Years 2 and 3 for a Callable Bond: (a) Nodes Where the Call Option Is Not Exercised and (b) Selected Nodes Where the Call Option Is Exercised

bond prior to the maturity date. The analysis of the puttable bond follows closely that of the callable bond. In the case of the puttable, we must establish the rule by which the decision to put is made. The reasoning is similar to that for the callable bond. If the PV of the future cash flows is less than the put price (that is, par), then the bond will be put. In equation form,

$$V_t = \text{Max}[\text{Put Price}, \text{PV}(\text{Future Cash Flows})]$$

Figure 4 is analogous to Figure 3. It shows the binomial tree with the values based on whether or not the investor exercises the put option at each node. The bond is puttable any time after the first year at par. The value of the bond is 105.327. Note that the value is greater than the value of the corresponding option-free bond.

With the two values in hand, we can calculate the value of the put option. Since the value of the puttable bond is 105.327 and the value of the

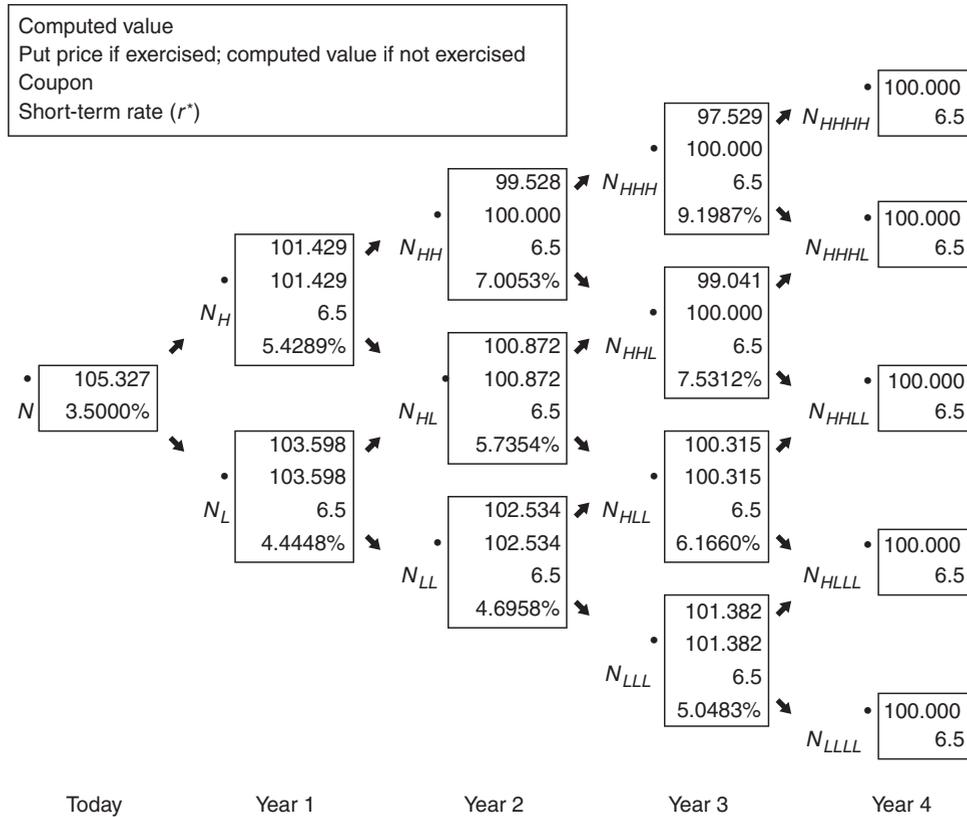

Figure 4 Valuing a Puttable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Puttable after the First Year at 100 (10% Volatility Assumed)

corresponding option-free bond is 104.643, the value of the embedded put option purchased by the investor is effectively 0.684.

Suppose that a bond is both puttable and callable. The procedure for valuing such a structure is to adjust the value at each node to reflect whether the issue would be put or called. Specifically, at each node there are two decisions about the exercising of an option that must be made. If it is called, the value at the node is replaced by the call price. The valuation procedure then continues using the call price at that node. If the call option is not exercised at a node, it must be determined whether or not the put option will be exercised. If it is exercised, then the put price is substituted at that node and is used in subsequent calculations.

FLOATING-COUPON BONDS WITH EMBEDDED OPTIONS

Simple discounted cash flow methods of analysis fail to handle floaters with embedded or option-like features. In this section we demonstrate how to use the lattice model to value (1) a *capped floater*, and (2) a *callable capped floater*. We will streamline the notation used in the binomial tree in the figures shown in this section.

Valuing Capped Floating-Rate Bonds

Consider a floating-rate bond with a coupon indexed to the 1-year rate (the reference rate) plus a spread. For our purposes, assume a 25

basis point (bp) spread to the reference rate. The coupon adjusts at each node to reflect the level of the reference rate plus the spread.

Using the same valuation method as before, we can find the value at each node. Recall the value of the bond is 100 (par) at the end of year 4. Consider N_{HLL} .

$$N_{HLL} = \frac{1}{2} \left[\frac{100 + 6.416}{1.06166} + \frac{100 + 6.416}{1.06166} \right] = 100.235$$

Stepping back one period

$$N_{LL} = \frac{1}{2} \left[\frac{100.235 + 4.9458}{1.046958} + \frac{100.238 + 4.9458}{1.046958} \right] = 100.465$$

Following this same procedure, we arrive at the price of 100.893. How would this

change if the interest rate on the bond were capped?

Assume that the cap is 7.25%. In Figure 5 we've taken the tree from Figure 1 and, as was the case with the optionless fixed-coupon bond, at each node we've entered the cash flow expected at the end of each period based on the reset formula. As rates move higher there is a possibility that the current reference rate exceeds the cap. Such is the case at N_{HHH} and N_{HLL} . The coupon is subject to the following constraint:

$$C_t = \text{Min}[r_t, 7.25\%]$$

As a result of the cap, the value of the bond in the upper nodes at $t = 3$ falls below par. For example,

$$N_{HHH} = \frac{1}{2} \left[\frac{100 + 7.25}{1.091987} + \frac{100 + 7.25}{1.09198} \right] = 98.215$$

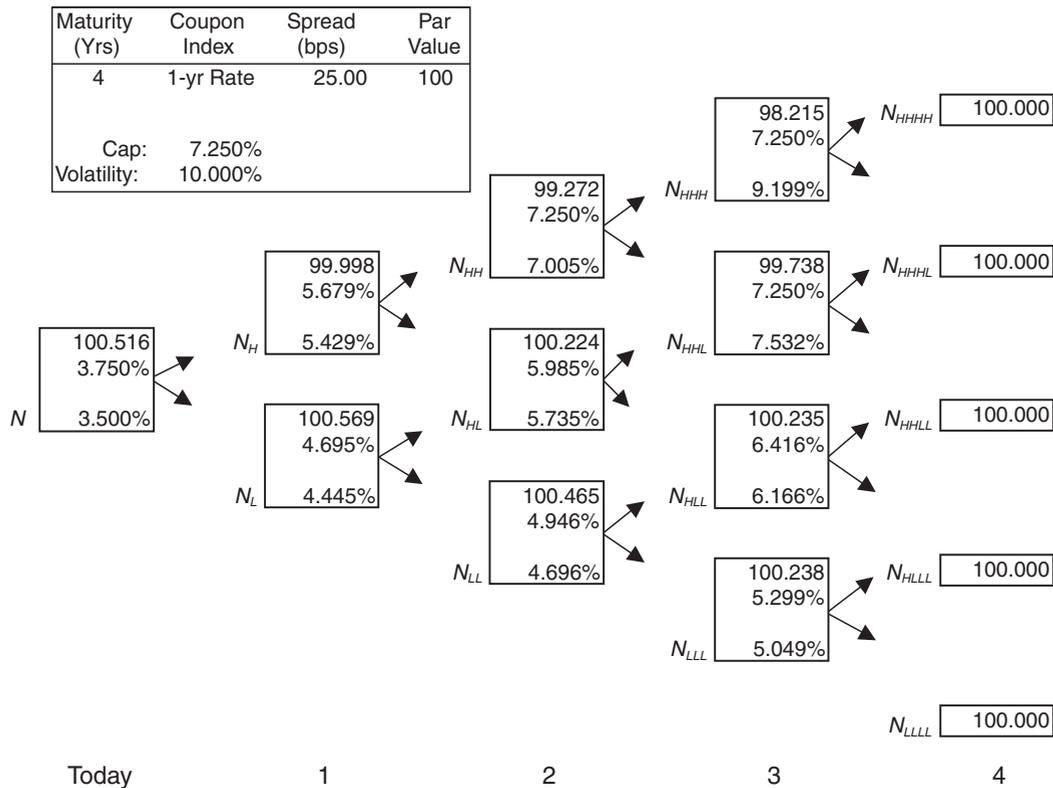

Figure 5 Valuation of a Capped Floating-Rate Bond

Valuing recursively through the tree, we arrive at the current value of the capped floater, 100.516, a value lower than the plain vanilla floater. This last calculation gives us a means for pricing the embedded option. Without a cap, the bond is priced at 100.893. The difference between these two prices is the value of the cap, 0.377. It is important to note that the price of the cap is volatility dependent. Any change in the volatility would result in a different valuation for the cap. The greater the volatility, the higher the price of the option, and vice versa.

We can extend the application of the lattice to the initial pricing of securities. What if an issuer wanted to offer this bond at par? In such a case, an adjustment has to be made to the coupon. To lower the price from 100.516 to par, a lower spread over the reference rate is offered to investors. Figure 6 shows the relationship between the spread over the 1-year reference rate and the bond price. At a spread of 8.70 bps over the 1-year reference rate, the capped floater in Figure 5 will be priced at par. Again, the spread of 8.7 bps is volatility dependent.

Callable Capped Floating-Rate Bonds

Now consider a call option on the capped floater. As was the case for a fixed-coupon bond, we must be careful to specify the appropriate rules for calling the bond on the valuation tree. It turns out that the rule is the same for floaters and fixed-coupon bonds. Any time the bond

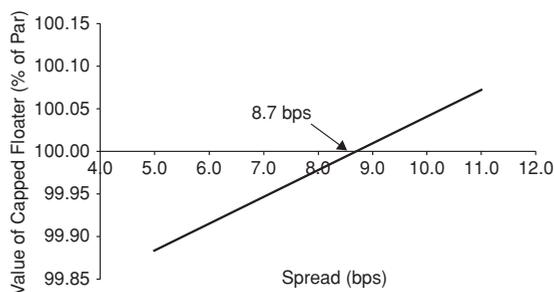

Figure 6 Spread to Index to Price Cap at Par

has a PV above par at a node where the bond is callable, the bond will be called. (Here we assume a par call to simplify the illustration.)

Before we get into the details, it is important to motivate the need for a call on a floating-rate bond. The value of a cap to the issuer increases as market rates near the cap and there is the potential for rates to exceed the cap prior to maturity. As rates decline, so does the value of the cap. The problem for the issuer in the event of low rates is the additional basis-point spread it is paying for a cap that now has little or no value. Thus, when rates decline, a call has value to the issuer because it can call and reissue at a different spread.

Suppose that the capped floater is callable at par anytime after the first year. Figure 7 provides details on the effect of the call option on valuation of the capped floater. Again, for a callable bond, when the present value exceeds par in a recursive valuation model, the bond is called. In the case of our 4-year bond, in Figure 7 the value of the bond at several lower nodes is now 100, the call price. The full effect of the call option on price is evident with today's price for the bond moving to 99.9140.

The by-product of this analysis is the value of the call option on a capped floater. We now have the fair value of the capped floater versus the callable capped floater. So the call option has a value of $100.516 - 100.189 = 0.327$.

How would one structure the issue so that it is priced at par? We have to offer a lower spread over the floating rate than the holder is already receiving for accepting the cap. In this case, we need to move the total spread over the 1-year floating rate to 13.37 bps. Figure 8 shows the relationship between spread and value.

VALUING CAPS AND FLOORS

An *interest rate cap* is nothing more than a package or strip of options. More specifically, a cap is a strip of European options on interest rates.

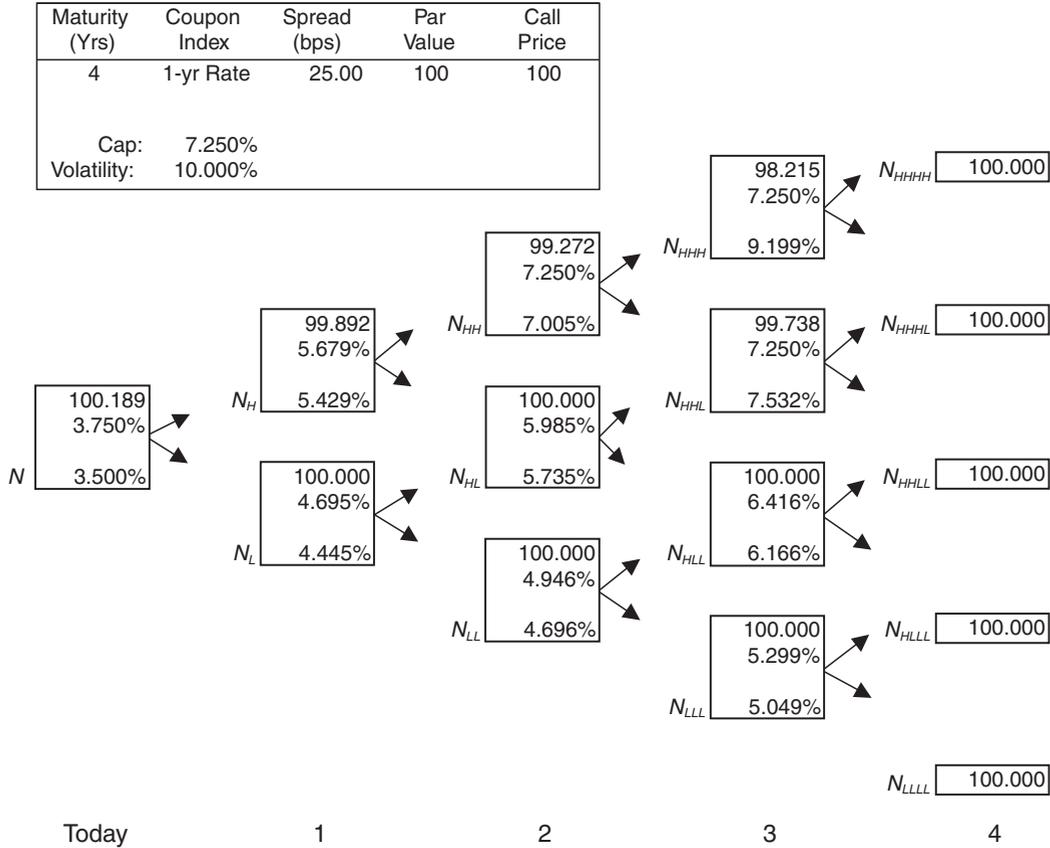

Figure 7 Valuation of a Capped Floating-Rate Bond

Thus, to value a cap, the value of each period's cap, called a caplet, is found and all the caplets are then summed.

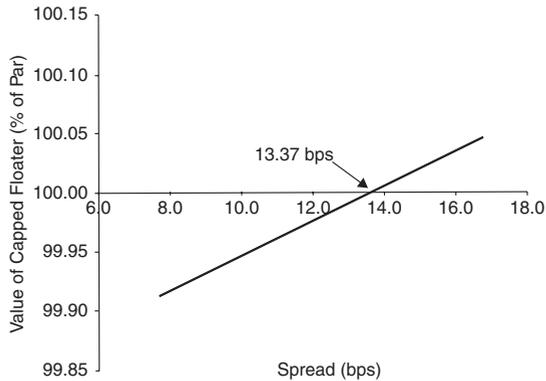

Figure 8 Spread to Index to Price Callable Cap at Par

In order to value caps and floors, a modification of the lattice framework is required. The modification is necessary because of the timing of the payments for a cap and floor: Settlement for the typical cap and floor is paid in arrears. Payment in arrears means that the interest rate paid is determined at the beginning of the period, but the actual payment is made at the end of the period (that is, beginning of the next period). This modification complicates the notation and will not be made here but is explained in Fabozzi (2006).

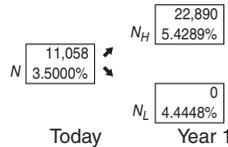

To illustrate, we once again use the binomial tree given in Figure 1 to value a cap. Consider a 5.2% 3-year cap with a notional amount of \$10 million. The reference rate is the 1-year rate. The payoff for the cap is annual.

The three panels in Figure 9 show how this cap is valued by valuing the three caplets. The value for the caplet for any year, say year X, is found as follows. First, calculate the payoff in year X at each node as either:

1. Zero if the one-year rate at the node is less than or equal to 5.2%, or
2. The notional amount of \$10 million times the difference between the 1-year rate at the node and 5.2% if the 1-year rate at the node is greater than 5.2%.

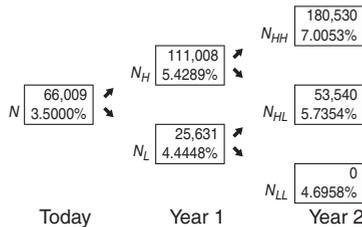

Assumptions:
 Cap rate: 5.2%
 Notional amount: \$10,000,000
 Payment frequency: Annual

Panel A: The Value of the Year 1 Caplet

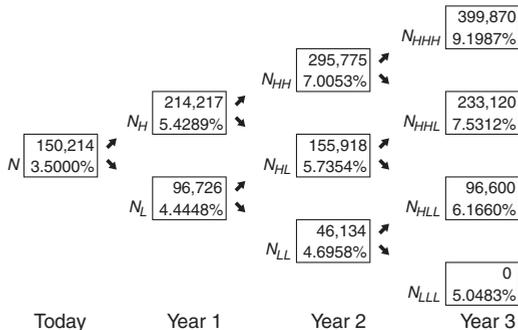

Value of Year 1 caplet = \$11,058

Panel B: The Value of the Year 2 Caplet

Value of Year 2 caplet = \$66,009

Panel C: The Value of the Year 3 Caplet

Value of Year 3 caplet = \$150,214

Summary: Value of 3-Year Cap = \$11,058 + \$66,009 + \$150,214 = \$227,281

Note on calculations: Payoff in last box of each figure is \$10,000,000 Maximum [(Rate at node - 5.2%), 0]

Then, the recursive valuation process is used to determine the value of the year X caplet.

For example, consider the year 3 caplet. At the top node in year 3 of Panel C of Figure 9, the 1-year rate is 9.1987%. Since the 1-year rate at this node exceeds 5.2%, the payoff in year 3 is:

$$\$10,000,000 \times (0.091987 - 0.052) = \$399,870$$

For node N_{HH} we look at the value for the cap at the two nodes to its right, N_{HHH} and N_{HHL} . Discounting the values at these nodes, \$399,870 and \$233,120, by the interest rate from the binomial tree at node N_{HH} , 7.0053%, we arrive at a value of \$295,755. That is,

$$\begin{aligned} \text{Value at } N_{HH} &= [\$399,870/(1.070053) \\ &\quad + \$233,120(1.070053)]/2 \\ &= \$295,775 \end{aligned}$$

The values at nodes N_{HH} and N_{HL} are discounted at the interest rate from the binomial tree at node N_H , 5.4289%, and then the value is computed. That is,

$$\begin{aligned} \text{Value at } N_H &= [\$295,775/(1.054289) \\ &\quad + \$155,918/(1.054289)]/2 \\ &= \$214,217 \end{aligned}$$

Finally, we get the value at the root, node N , which is the value of the year 3 caplet found by discounting the value at N_H and N_L by 3.5% (the interest rate at node N). Doing so gives:

$$\begin{aligned} \text{Value at } N &= [\$214,217/(1.035) \\ &\quad + \$96,726/(1.035)]/2 \\ &= \$150,214 \end{aligned}$$

Following the same procedure, the value of the year 2 caplet is \$66,009 and the value of the year 1 caplet is \$11,058. The value of the cap is then the sum of the three caplets.

Thus, the value of the cap is \$227,281, found by adding \$11,058, \$66,009, and \$150,214. The

Figure 9 Valuation of a Three-Year 5.2% Cap (10% Volatility Assumed)

valuation of an *interest rate floor* is done in the same way.

VALUATION OF TWO MORE EXOTIC STRUCTURES

The lattice-based recursive valuation methodology is robust. To further support this claim, we address the valuation of two more exotic structures—the step-up callable note and the range floater.

Valuing a Step-Up Callable Note

Step-up callable notes are callable instruments whose coupon rate is increased (that is, “stepped up”) at designated times. When the coupon rate is increased only once over the security’s life, it is said to be a single step-up callable note. A multiple step-up callable note is a step-up callable note whose coupon is increased more than one time over the life of the security. Valuation using the lattice model is similar to that for valuing a callable bond

described above except that the cash flows are altered at each node to reflect the coupon characteristics of a step-up note.

Suppose that a four-year step-up callable note pays 4.25% for two years and then 7.5% for two more years. Assume that this note is callable at par at the end of year 2 and year 3. We will use the binomial tree given in Figure 1 to value this note.

Figure 10 shows the value of the note if it were not callable. The valuation procedure is the recursive valuation from Figure 2. The coupon in the box at each node reflects the step-up terms. The value is 102.082. Figure 11 shows that the value of the single step-up callable note is 100.031. The value of the embedded call option is equal to the difference in the optionless step-up note value and the step-up callable note value, 2.051.

Now we move to another structure where the coupon floats with a reference rate, but is restricted. In this next case, a range is set in which the bond pays the reference rate when the rate falls within a specified range, but outside the range no coupon is paid.

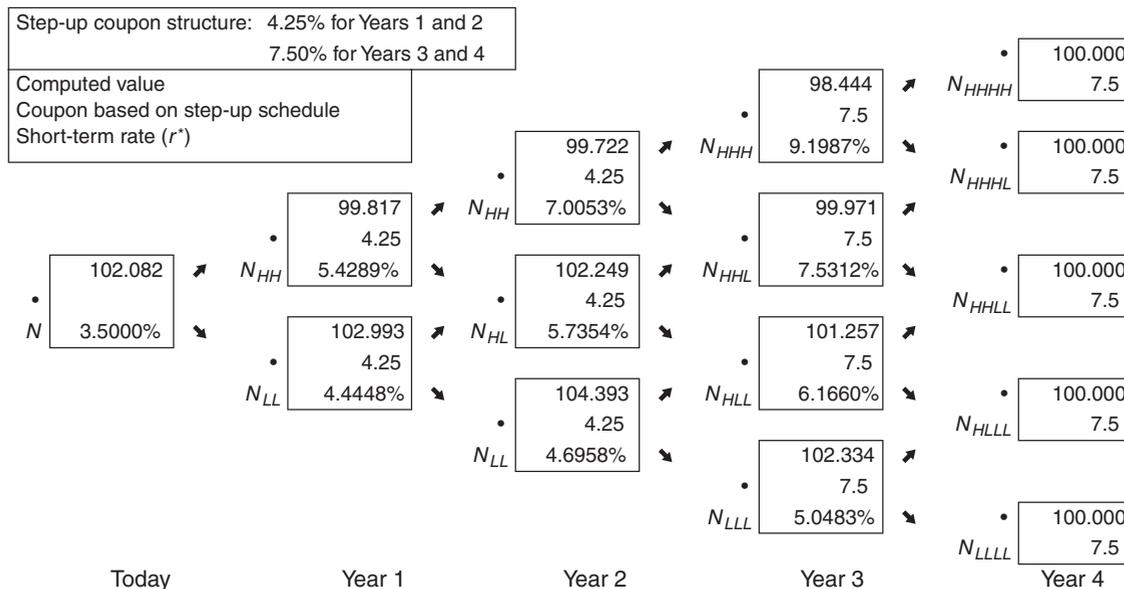

Figure 10 Valuing a Single Step-Up Noncallable Note with Four Years to Maturity (10% Volatility Assumed)

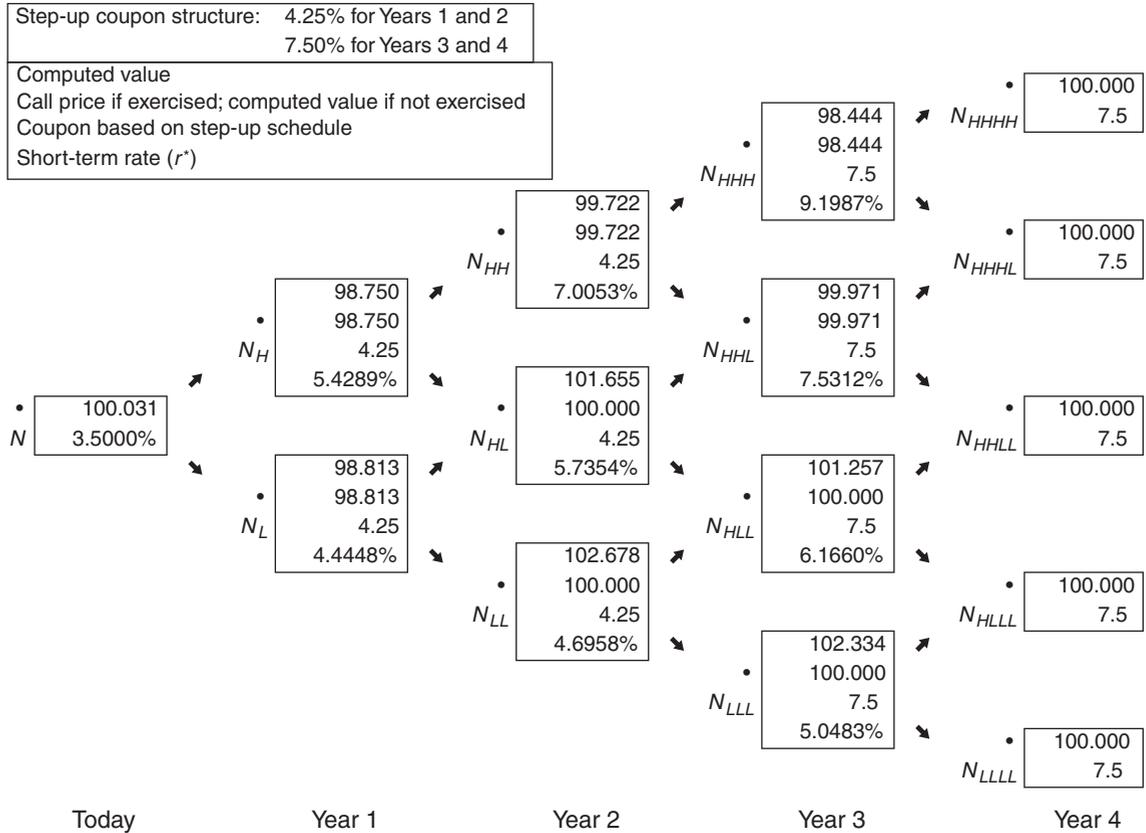

Figure 11 Valuing a Single Step-Up Callable Note with Four Years to Maturity, Callable in Two Years at 100 (10% Volatility Assumed)

Valuing a Range Note

A *range note* is a security that pays the reference rate only if the rate falls within a band. If the reference rate falls outside the band, whether the lower or upper boundary, no coupon is paid. Typically, the band increases over time.

To illustrate, suppose that the reference rate is, again, the 1-year rate and the note has three years to maturity. Suppose further that the band (or coupon schedule) is defined as in Table 2. Figure 12 shows the interest rate tree and the cash flows expected at the end of each year. Ei-

Table 2 Coupon Schedule (Bands) for a Range Note

	Year 1	Year 2	Year 3
Lower Limit	3.00%	4.00%	5.00%
Upper Limit	5.00%	6.25%	8.00%

ther the 1-year reference rate is paid, or nothing. In the case of this 3-year note, there is only one state in which no coupon is paid. Using our recursive valuation method, we can work back through the tree to the current value, 98.963.

VALUING AN OPTION ON A BOND

Thus far we have seen how the lattice can be used to value bonds with embedded options. The same tree can be used to value a stand-alone *option on a bond*.

To illustrate how this is done, consider a 2-year American call option on a 6.5% 2-year Treasury bond with a strike price of 100.25 which will be issued two years from now. We will assume that the on-the-run Treasury yields are

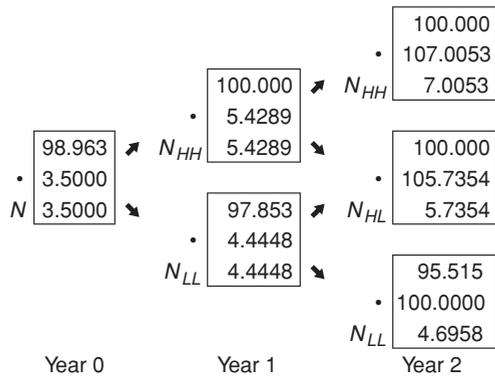

Figure 12 Valuation of a Three-Year Range Floater

those represented in Figure 13. Within the binomial tree we find the value of the Treasury bond at each node. Figure 14 shows the value of our hypothetical Treasury bond (excluding coupon interest) at each node at the end of year 2.

The decision rule at a node for determining the value of an option on a bond depends on whether or not the call or put option being valued is in the money. Moreover, the exercise decision is only applied at the expiration date. That is, a call option will be exercised at the option's expiration date if the bond's value at a node is greater than the strike price. In the case of a put option, the option will be exercised if the strike price at a node is greater than the bond's value (that is, if the put option is in the money).

Three values for the underlying 2-year bond are shown in Figure 14: 97.925, 100.418, and

102.534. Given these three values, the value of a call option with a strike price of 100.25 can be determined at each node. For example, if in year 2 the price of this Treasury bond is 97.925, then the value of the call option would be zero. In the other two cases, since the value at the end of year 2 is greater than the strike price, the value of the call option is the difference between the price of the bond at the node and 100.25.

Given these values, the binomial tree is used to find the present value of the call option using recursive valuation. The discount rates are the now familiar 1-year forward rates from the binomial tree. The expected value at each node for year 1 is found by discounting the call option value from year 2 using the rate at the node. Move back one more year to "Today." The value of the option is 0.6056.

The same procedure is used to value a put option on a bond.

EXTENSIONS

We next demonstrate how to compute the option-adjusted spread, effective duration, and the convexity for a fixed income instrument with an embedded option.

Option-Adjusted Spread

We have concerned ourselves with valuation to this point. However, financial market transactions determine the actual price for a fixed

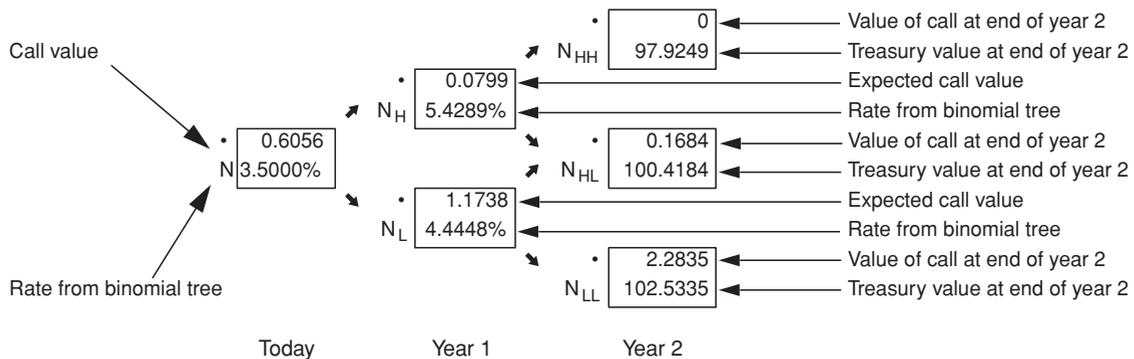

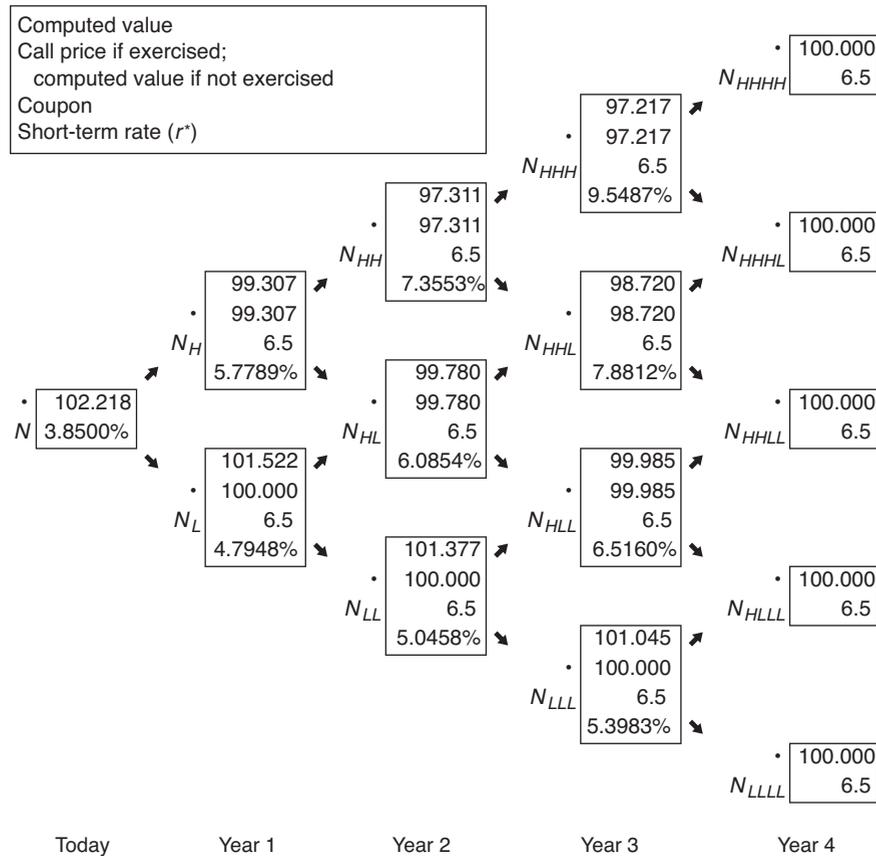

Figure 13 Using the Arbitrage-Free Binomial Method
 Expiration: 2 years; Strike Price: 100.25; Current Price: 104.643; Volatility Assumption: 10%

* Each 1-year rate is 35 basis points greater than in Figure 1.

Figure 14 Demonstration That the Option-Adjusted Spread is 35 Basis Points for a 6.5% Callable Bond Selling at 102.218 (Assuming 10% Volatility)

income instrument, not a series of calculations on an interest rate lattice. If markets are able to provide a meaningful price (usually a function of the liquidity of the market in which the instrument trades), this price can be translated into an alternative measure of relative value, the *option-adjusted spread* (OAS).

The OAS for a security is the fixed spread (usually measured in basis points) over the benchmark rates that equates the output from the valuation process with the actual market price of the security.² For an optionless security, the calculation of OAS is a relatively simple iterative process. The process is much more analytically challenging with the added complexity of optionality. And, just as the value of the op-

tion is volatility dependent, the OAS for a fixed income security with embedded options or an option-like interest rate product is volatility dependent.

Recall our illustration in Figure 2 where the value of a callable bond was calculated as 102.899. Suppose that we had information from the market that the price is actually 102.218. We need the OAS that equates the value from the lattice with the market price. Since the market price is lower than the valuation, the OAS is a positive spread to the rates in the figure, rates which we assume to be benchmark rates.

The solution in this case is 35 basis points, which is incorporated into Figure 14 that shows the value of the callable bond after adding

35 basis points to each rate. The simple, binomial tree provides evidence of the complex calculation required to determine the OAS for a callable bond. In Figure 2, the bond is called at N_{HLL} . However, once the tree is shifted 35 bps in Figure 14, the PV of future cash flows at N_{HLL} falls below the call price to 99.985, so the bond is not called at this node. Hence, as the lattice structure grows in size and complexity, the need for computer analytics becomes obvious.

Effective Duration and Effective Convexity

Duration and convexity provide a measure of the interest rate risk inherent in a fixed income security.³ We rely on the lattice model to calculate the *effective duration* and *effective convexity* of a bond with an embedded option and other option-like securities. The formulas for these two risk measures are given below:

$$\text{Effective duration} = \frac{V_- - V_+}{2 V_0(\Delta r)}$$

$$\text{Effective convexity} = \frac{V_+ - V_- - 2V_0}{2 V_0(\Delta r)^2}$$

where V_- and V_+ are the values derived following a parallel shift in the yield curve down and up, respectively, by a fixed spread. The model adjusts for the changes in the value of the embedded call option that result from the shift in the curve in the calculation of V_- and V_+ .

Note that the calculations must account for the OAS of the security. Below we provide the steps for the proper calculation of V_+ . The calculation for V_- is analogous.

Step 1: Given the market price of the issue, calculate its OAS.

Step 2: Shift the on-the-run yield curve up by a small number of basis points (Δr).

Step 3: Construct a binomial interest rate tree based on the new yield curve from Step 2.

Step 4: Shift the binomial interest rate tree by the OAS to obtain an “adjusted tree.” That

is, the calculation of the effective duration and convexity assumes a constant OAS.

Step 5: Use the adjusted tree in Step 4 to determine the value of the bond, V_+ .

We can perform this calculation for our 4-year callable bond with a coupon rate of 6.5%, callable at par selling at 102.218. We computed the OAS for this issue as 35 basis points. Figure 15 shows the adjusted tree following a shift in the yield curve up by 25 basis points, and then adding 35 basis points (the OAS) across the tree. The adjusted tree is then used to value the bond. The resulting value, V_+ is 101.621.

To determine the value of V_- , the same five steps are followed except that in Step 2, the on-the-run yield curve is shifted down by the same number of basis points (Δr). It can be demonstrated that for our callable bond, the value for V_- is 102.765.

The results are summarized below:

$$\Delta r = 0.0025$$

$$V_+ = 101.621$$

$$V_- = 102.765$$

$$V_0 = 102.218$$

Therefore,

$$\text{effective duration} = \frac{102.765 - 101.621}{2(102.218)(0.0025)} = 2.24$$

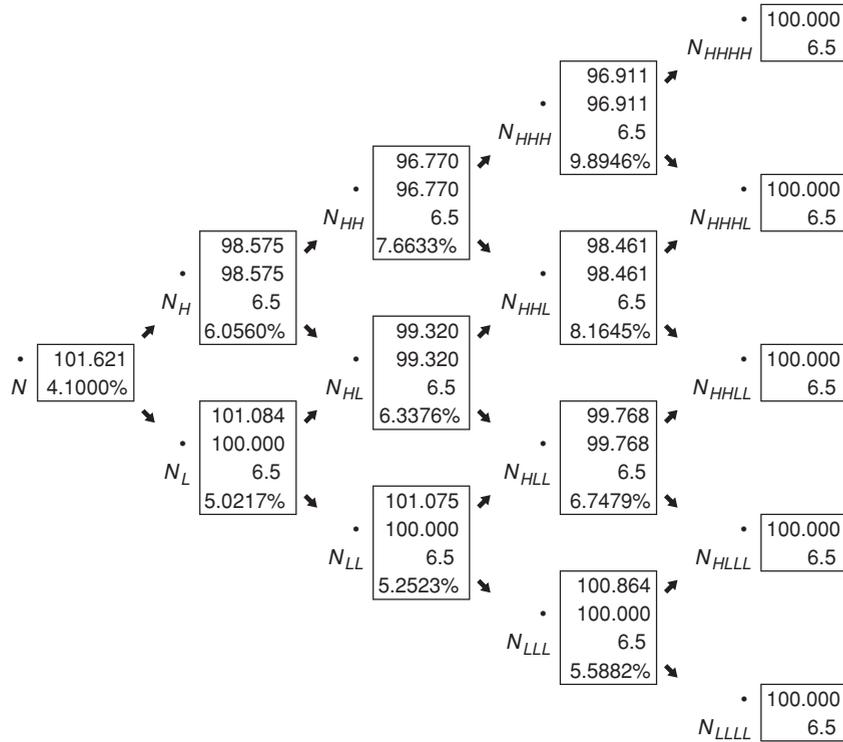

$$\text{Effective convexity} = \frac{101.621 + 102.765 - 2(102.218)}{2(102.218)(0.0025)^2}$$

$$= -39.1321$$

Notice that this callable bond exhibits negative convexity.

KEY POINTS

- The valuation of an option-free bond is straightforward. However, once there is a provision in the bond structure that grants the issuer and/or the investor an option, valuation becomes more difficult.
- The standard technology employed to value bonds with embedded options that depend

* +25 basis point shift in on-the-run yield curve.

Figure 15 Determination of V_+ for Calculating Effective Duration and Convexity*

on future interest rates, such as callable and puttable bonds, is the lattice framework.

- The initial step in the lattice approach is to generate an arbitrage-free lattice or interest rate tree from an appropriate on-the-run yield curve.
- Based on rules specified by the modeler for when an option will be exercised, a lattice of future cash flows is obtained and then valued using the interest rates in the lattice.
- The same model is used to value interest rate-sensitive derivatives such as options on bonds, interest rate caps, and interest rate caps and floors.
- Other useful analytical measures can be obtained using the lattice model. These measures include the option-adjusted spread—a measure of relative value—and effective duration and effective convexity—measures of price sensitivity to changes in interest rates.

Understanding the Building Blocks for OAS Models

PHILIP O. OBAZEE

Senior Vice President and Head of Derivatives,
Delaware Investments

Abstract: Ubiquity of option-adjusted spread (OAS) in finance practice is remarkable, in light of the fact that there is no general consensus on its implementation. Investors in mortgage-backed (MBS) and asset-backed (ABS) securities hold a long position in noncallable bonds and short positions in prepayment (call) options. The noncallable bond is a bundle of zero coupon bonds, and the call option gives the borrower the right to prepay the loan at any time prior to the scheduled principal repayment dates. The call option component of the valuation consists of intrinsic and time values. To the extent that the option embedded in ABS/MBS is a delayed American exercise style, the time value component associated with prepayment volatility needs to be evaluated. To evaluate this option, OAS analysis uses an option-based technique to price ABS/MBS under different interest rate scenarios. Hence, OAS is the spread differential between the zero volatility spread and option value components of an ABS/MBS.

Investors and analysts continue to wrestle with the differences in option-adjusted-spread (OAS) values for securities they see from competing dealers and vendors. And portfolio managers continue to pose fundamental questions about OAS with which we all struggle in the financial industry. Some of the frequently asked questions are

- How can we interpret the difference in dealers' OAS values for a specific security?
- What is responsible for the differences?
- Is there really a correct OAS value for a given security?

In this entry, we examine some of the questions about OAS analysis, particularly the basic building block issues about OAS implementa-

tion. Because some of these issues determine "good or bad" OAS results, we believe there is a need to discuss them. To get at these fundamental issues, we hope to avoid sounding pedantic by relegating most of the notations and expressions to the endnotes.

Clearly, it could be argued that portfolio managers do not need to understand the OAS engine to use it but that they need to know how to apply it in relative value decisions. This argument would be correct if there were market standards for representing and generating interest rates and prepayments. In the absence of a market standard, investors need to be familiar with the economic intuitions and basic assumptions made by the underlying models. More important, investors need to understand what

works for their situation and possibly identify those situations in which one model incorrectly values a bond. Although pass-throughs are commoditized securities, OAS results still vary considerably from dealer to dealer and vendor to vendor. This variance is attributable to differences in the implementation of the respective OAS models.

Unlike other market measures, for example, yield to maturity and the weighted average life of a bond, which have market standards for calculating their values, OAS calculations suffer from the lack of a standard and a black-box mentality. The lack of a standard stems from the required inputs in the form of interest rate and prepayment models that go into an OAS calculation. Although there are many different interest rate models available, there is little agreement on which one to use. Moreover, there is no agreement on how to model prepayments. The black-box mentality comes from the fact that heavy mathematical machinery and computational algorithms are involved in the development and implementation of an OAS model. This machinery is often so cryptic that only a few initiated members of the intellectual tribe can decipher it. In addition, dealers invest large sums in the development of their term structures and prepayment models and, consequently, they are reluctant to share it.

In this entry, we review some of the proposed term structures and prepayments. Many of the term structure models describe “what is” and only suggest that the models could be used. Which model to use perhaps depends on the problem at hand and the resources available. In this entry, we review some of the popular term structure models and provide some general suggestions on which ones should not be used.

Investors in asset-backed securities (ABS) and mortgage-backed securities (MBS) hold long positions in noncallable bonds and short positions in call (prepayment) options. The noncallable bond is a bundle of zero-coupon bonds (e.g., Treasury strips), and the call option gives

the borrower the right to prepay the mortgage at any time prior to the maturity of the loan. In this framework, the value of MBS is the difference between the value of the noncallable bond and the value of the call (prepayment) option. Suppose a theoretical model is developed to value the components of ABS/MBS. The model would value the noncallable component, which we loosely label the zero volatility component, and the call option component. If interest rate and prepayment risks are well accounted for, and if those are the only risks for which investors demand compensation, one would expect the theoretical value of the bond to be equal to its market value. If these values are not equal, then market participants demand compensation for the unmodeled risks. One of these unmodeled risks is the forecast error associated with the prepayments. By this, we mean the actual prepayment may be faster or slower than projected by the model. Other unmodeled risks are attributable to the structure and liquidity of the bond. In this case, OAS is the market price for the unmodeled risks.

To many market participants, however, OAS indicates whether a bond is mispriced. All else being equal, given that interest rate and prepayment risks have been accounted for, one would expect the theoretical price of a bond to be equal to its market price. If these two values are not equal, a profitable opportunity may exist in a given security or a sector. Moreover, OAS is viewed as a tool that helps identify which securities are cheap or rich when the securities are relatively priced.

The zero volatility component of ABS/MBS valuation is attributable to the pure interest rate risk of a known cash flow—a noncallable bond. The forward interest rate is the main value driver of a noncallable bond. Indeed, the value driver of a noncallable bond is the sum of the rolling yield and the value of the convexity. The rolling yield is the return earned if the yield curve and the expected volatility are unchanged. Convexity refers to the curvature of the price-yield curve. A noncallable bond

exhibits varying degrees of positive convexity. Positive convexity means a bond's price rises more for a given yield decline than it falls for the same yield. By unbundling the noncallable bond components in ABS/MBS to their zero-coupon bond components, the rolling yield becomes dominant. Hence, it is called the zero volatility component—that is, the component of the yield spread that is attributable to no change in the expected volatility.

The call option component in ABS/MBS valuation consists of intrinsic and time values. To the extent the option embedded in ABS/MBS is the delayed American exercise style—in other words, the option is not exercised immediately but becomes exercisable any time afterward—the time value component dominates. Thus, in valuing ABS/MBS, the time value of the option associated with the prepayment volatility needs to be evaluated. To evaluate this option, OAS analysis uses an option-based technique to evaluate ABS/MBS prices under different interest rate scenarios. OAS is the spread differential between the zero volatility and option value components of MBS. These values are expressed as spreads measured in basis points.

The option component is the premium paid (earned) from going long (shorting) a prepayment option embedded in the bond. The bondholders are short the option, and they earn the premium in the form of an enhanced coupon. Mortgage holders are long the prepayment option, and they pay the premium in spread above the comparable Treasury. The option component is the cost associated with the variability in cash flow that results from prepayments over time.

The two main inputs into the determination of an OAS of a bond are as follows:

- Generate the cash flow as a function of the principal (scheduled and unscheduled) and coupon payments.
- Generate interest rate paths under an assumed term structure model.

At each cash flow date, a spot rate determines the discount factor for each cash flow. The present value of the cash flow is equal to the sum of the product of the cash flow and the discount factors.¹ When dealing with a case in which uncertainty about future prospects is important, the cash flow and the spot rate need to be specified to account for the uncertainty.² The cash flow and spot rate become a function of time and the state of the economy. The time consideration is that a dollar received now is worth more than one received tomorrow. The state of the economy consideration accounts for the fact that a dollar received in a good economy may be perceived as worth less than a dollar earned in a bad economy. For OAS analysis, the cash flow is run through different economic environments represented by interest rates and prepayment scenarios. The spot rate, which is used to discount the cash flow, is run through time steps and interest rate scenarios. The spot rate represents the instantaneous rate of risk-free return at any time, so that \$1 invested now will have grown by a later time to \$1 multiplied by a continuously compounded rollover rate during the time period.³ Arbitrage pricing theory stipulates the price one should pay now to receive \$1 at later time is the expected discount of the payoff.⁴ So by appealing to the arbitrage pricing theory, we are prompted to introduce an integral representation for the value equation; in other words, the arbitrage pricing theory allows us to use the value additivity principle across all interest rate scenarios.

IS IT EQUILIBRIUM OR AN ARBITRAGE MODEL?

Market participants are guided in their investment decision making by received economic philosophy or intuition. Investors, in general, look at value from either an absolute or relative value basis. Absolute value basis proceeds from the economic notion that the market clears at an exogenously determined price

that equates supply-and-demand forces. Absolute valuation models are usually supported by general or partial *equilibrium* arguments. In implementing market measure models that depend on equilibrium analysis, the role of an investor's preference for risky prospects is directly introduced. The formidable task encountered with respect to preference modeling and the related aggregation problem has rendered these types of models useless for most practical considerations. One main exception is the present value rule that explicitly assumes investors have a time preference for today's dollar. Where the present value function is a monotonically decreasing function of time, today's dollar is worth more than a dollar earned tomorrow. Earlier term structure models were supported by equilibrium arguments, for example, the Cox-Ingersoll-Ross (CIR) model.⁵ In particular, CIR provides an equilibrium foundation for a class of yield curves by specifying the endowments and preferences of traders, which, through the clearing of competitive markets, generates the proposed term structure model.

Relative valuation models rely on *arbitrage* and dominance principles and characterize asset prices in terms of other asset prices. A well-known example of this class is the Black-Scholes⁶ and Merton⁷ option pricing model. Modern term structure models, for example, Hull-White,⁸ Black-Derman-Toy (BDT),⁹ and Heath-Jarrow-Morton (HJM),¹⁰ are based on arbitrage arguments. Although relative valuation models based on arbitrage principles do not directly make assumptions about investors' preferences, there remains a vestige of the continuity of preference, for example, the notion that investors prefer more wealth to less. Thus, whereas modelers are quick in attributing "arbitrage-freeness" to their models, assuming there are no arbitrage opportunities implies a continuity of preference that can be supported in equilibrium. So, if there are no arbitrage opportunities, the model is in equilibrium for some specification of endowments and preferences. The upshot is that the distinc-

tion between equilibrium models and arbitrage models is a stylized fetish among analysts to demarcate models that explicitly specify endowment and preference sets (equilibrium) and those models that are outwardly silent about the preference set (arbitrage). Moreover, analysts usually distinguish equilibrium models as those that use today's term structure as an output and no-arbitrage models as those that use today's term structure as an input.

Arbitrage opportunity exists in a market model if there is a strategy that guarantees a positive payoff in some state of the world with no possibility of negative payoff and no initial net investment. The presence of arbitrage opportunity is inconsistent with economic equilibrium populated by market participants that have increasing and continuous preferences. Moreover, the presence of arbitrage opportunity is inconsistent with the existence of an optimal portfolio strategy for market participants with nonsatiated preferences (prefer more to less) because there would be no limit to the scale at which they want to hold an arbitrage position. The economic hypothesis that maintains two perfect substitutes (two bonds with the same credit quality and structural characteristics issued by the same firm) must trade at the same price is an implication of no arbitrage. This idea is commonly referred to as the law of one price. Technically speaking, the fundamental theorem of asset pricing is a collection of canonical equivalent statements that implies the absence of arbitrage in a market model. The theorem provides for weak equivalence between the absence of arbitrage, the existence of a linear pricing rule, and the existence of optimal demand from some market participants who prefer more to less. The direct consequence of these canonical statements is the pricing rule: the existence of a positive linear pricing rule, the existence of positive risk-neutral probabilities, and associated riskless rate or the existence of a positive state price density.

In essence, the pricing rule representation provides a way of correctly valuing a

security when the arbitrage opportunity is eliminated. A fair price for a security is the arbitrage-free price. The arbitrage-free price is used as a benchmark in relative value analysis to the extent that it is compared with the price observed in actual trading. A significant difference between the observed and arbitrage-free values may indicate the following profit opportunities:

- If the arbitrage price is above the observed price, all else being equal, the security is cheap and a long position may be called for.
- If the arbitrage price is below the observed price, all else being equal, the security is rich and a short position may be called for.

In practice, the basic steps in determining the arbitrage-free value of the security are as follows:

- Specify a model for the evolution of the underlying security price.
- Obtain a risk-neutral probability.
- Calculate the expected value at expiration using the risk-neutral probability.
- Discount this expectation using the risk-free rates.

In studying the solution to the security valuation problem in the arbitrage pricing framework, analysts usually use one of the following:

- Partial differential equation (PDE) framework
- Equivalent martingale measure framework

The PDE framework is a direct approach and involves constructing a risk-free portfolio, then deriving a PDE implied by the lack of arbitrage opportunity. The PDE is solved analytically or evaluated numerically.¹¹

Although there are few analytical solutions for pricing PDEs, most of them are evaluated using numerical methods such as lattice, finite difference, and Monte Carlo. The equivalent martingale measure framework uses the notion of arbitrage to determine a probability measure under which security prices are martingales once discounted. The new probability

measure is used to calculate the expected value of the security at expiration and discounting with the risk-free rate.

WHICH IS THE RIGHT MODEL OF THE INTEREST RATE PROCESS?

The bare essential of the bond market is a collection of zero-coupon bonds for each date, for example, now, that mature later. A zero-coupon bond with a given maturity date is a contract that guarantees the investor \$1 to be paid at maturity. The price of a zero-coupon bond at time t with a maturity date of T is denoted by $P(t, T)$. In general, analysts make the following simplifying assumptions about the bond market:

- There exists a frictionless and competitive market for a zero-coupon bond for every maturity date. By a frictionless market, we mean there is no transaction cost in buying and selling securities and there is no restriction on trades such as a short sale.
- For every fixed date, the price of a zero-coupon bond, $\{P(t, T); 0 \leq t \leq T\}$, is a stochastic process with $P(t, t) = 1$ for all t . By stochastic process, we mean the price of a zero-coupon bond moves in an unpredictable fashion from the date it was bought until it matures. The present value of a zero-coupon bond when it was bought is known for certain and it is normalized to equal one.
- For every fixed date, the price for a zero-coupon bond is continuous in that at every trading date the market is well bid for the zero-coupon bond.

In addition to zero-coupon bonds, the bond market has a money market (bank account) initialized with a unit of money.¹² The bank account serves as an accumulator factor for rolling over the bond.

A term structure model establishes a mathematical relationship that determines the price of a zero-coupon bond, $\{P(t, T); 0 \leq t \leq T\}$, for all dates t between the time the bond is bought (time 0) and when it matures (time T). Alternatively, the term structure shows the relationship between the yield to maturity and the time to maturity of the bond. To compute the value of a security dependent on the term structure, one needs to specify the dynamic of the interest rate process and apply an arbitrage restriction. A term structure model satisfies the arbitrage restriction if there is no opportunity to invest risk-free and be guaranteed a positive return.¹³

To specify the dynamic of the interest rate process, analysts have always considered a dynamic that is mathematically tractable and anchored in sound economic reasoning. The basic tenet is that the dynamic of interest rates is governed by time and the uncertain state of the world. Modeling time and uncertainty are the hallmarks of modern financial theory. The uncertainty problem has been modeled with the aid of the probabilistic theory of the stochastic process. The stochastic process models the occurrence of random phenomena; in other words, the process is used to describe unpredictable movements. The stochastic process is a collection of random variables that take values in the state space. The basic elements distinguishing a stochastic process are state space¹⁴ and index parameter,¹⁵ and the dependent relationship among the random variables (e.g., X_t).¹⁶ The Poisson process and Brownian motion are two fundamental examples of continuous time stochastic processes.

In everyday financial market experiences, one may observe, at a given instant, three possible states of the world: Prices may go up a tick, decrease a tick, or do not change. The ordinary market condition characterizes most trading days; however, security prices may from time to time exhibit extreme behavior. In financial modeling, there is the need to distinguish between rare and normal events. Rare events

usually bring about discontinuity in prices. The Poisson process is used to model jumps caused by rare events and is a discontinuous process. Brownian motion is used to model ordinary market events for which extremes occur only infrequently according to the probabilities in the tail areas of normal distribution.¹⁷

Brownian motion is a continuous martingale. Martingale theory describes the trend of an observed time series. A stochastic process behaves like a martingale if its trajectories display no discernible trends.

- A stochastic process that, on average, increases is called a submartingale.
- A stochastic process that, on average, declines is called a supermartingale.

Suppose one has an interest in generating a forecast of a process (e.g., R_t – interest rate) by expressing the forecast based on what has been observed about R based on the information available (e.g., F_t) at time t .¹⁸ This type of forecast, which is based on conditioning on information observed up to a time, has a role in financial modeling. This role is encapsulated in a martingale property.¹⁹ A martingale is a process, the expectation for which future values conditional on current information are equal to the value of the process at present. A martingale embodies the notion of a fair gamble: The expected gain from participating in a family of fair gambles is always zero and, thus, the accumulated wealth does not change in expectation over time. Note the actual price of a zero-coupon bond does not move like a martingale. Asset prices move more like sub-martingales or supermartingales. The usefulness of martingales in financial modeling stems from the fact that one can find a probability measure that is absolutely continuous with objective probability such that bond prices discounted by a risk-free rate become martingales. The probability measures that convert discounted asset prices into martingales are called equivalent martingale measures. The basic idea is that, in the absence of an arbitrage opportunity, one can

find a synthetic probability measure Q absolutely continuous with respect to the original measure P so that all properly discounted asset prices behave as martingales. A fundamental theorem that allows one to transform R_t into a martingale by switching the probability measure from P to Q is called the Girsanov theorem.

The powerful assertion of the Girsanov theorem provides the ammunition for solving a stochastic differential equation driven by Brownian motion in the following sense: By changing the underlying probability measure, the process that was driving the Brownian motion becomes, under the equivalent measure, the solution to the differential equation. In financial modeling, the analog to this technical result says that in a risk-neutral economy assets should earn a risk-free rate. In particular, in the option valuation, assuming the existence of a risk-neutral probability measure allows one to dispense with the drift term, which makes the diffusion term (volatility) the dominant value driver.

To model the dynamic of interest rates, it is generally assumed the change in rates over instantaneous time is the sum of the drift and diffusion terms (see Figure 1).²⁰ The drift term could be seen as the average movement of the process over the next instants of time, and the diffusion is the amplitude (width) of the movement. If the first two moments are sufficient to describe the distribution of the asset

return, the drift term accounts for the mean rate of return and the diffusion accounts for the standard deviation (volatility). Empirical evidence has suggested that interest rates tend to move back to some long-term average, a phenomenon known as mean reverting that corresponds to the Ornstein-Uhlenbeck process (see Figure 2).²¹ When rates are high, mean reversion tends to cause interest rates to have a negative drift; when rates are low, mean reversion tends to cause interest rates to have a positive drift.

The highlights of the preceding discussion are as follows:

- The modeler begins by decomposing bonds to their bare essentials, which are zero-coupon bonds.
- To model a bond market that consists of zero-coupon bonds, the modeler makes some simplifying assumptions about the structure of the market and the price behaviors.
- A *term structure model* establishes a mathematical relationship that determines the price of a zero-coupon bond and, to compute the value of a security dependent on the term structure, the modeler needs to specify the dynamic of the interest rate process and apply arbitrage restriction.
- The *stochastic process* is used to describe the time and uncertainty components of the price of zero-coupon bonds.

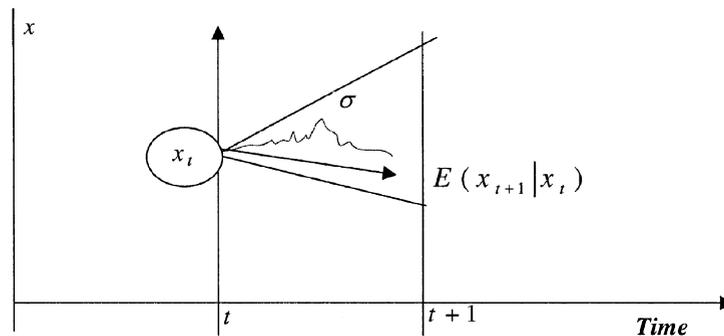

Figure 1 Drift and Diffusion

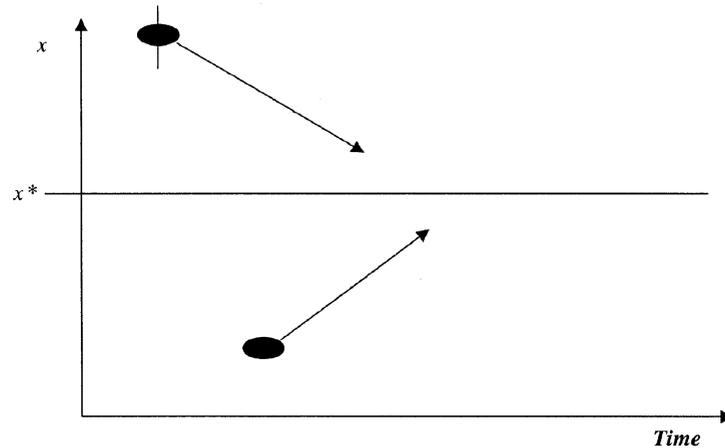

Figure 2 Process with Mean Reversion (Ornstein-Uhlenbeck Process)

- There are two basic types of stochastic processes used in financial modeling: The Poisson process is used to model jumps caused by rare events, and Brownian motion is used to model ordinary market events for which extremes occur only infrequently.
- We assume the market for zero-coupon bonds is well bid, that is, the zero-coupon price is continuous. Brownian motion is the suitable stochastic process to describe the evolution of interest rates over time. In particular, Brownian motion is a continuous martingale. Martingale theory describes the trend of the observed time series.
- Once we specify the evolution of interest rate movements, we need an arbitrage pricing theory that tells us the price one should pay now to receive \$1 later is an expected discounted payoff. The issue to be resolved is, What are the correct expected discount factors to use? The discount must be determined by the market and based on risk-adjusted probabilities. In particular, when all bonds are properly risk-adjusted, they should earn risk-free rates; if not, arbitrage opportunity exists to earn riskless profit.
- The risk-adjusted probability consistent with the no-arbitrage condition is the equivalent martingale measure; it is the probability mea-

sure that converts the discounted bond price to a martingale (fair price). The elegance of the martingale theory is the “roughs and tumbles” one finds in the world of partial differentiation are to some extent avoided and the integral representation it allows fits nicely with Monte Carlo simulations.

Several term structure models have been proposed with subtle differences. However, the basic differences amount to how the dynamic of the interest rate is specified, the number of factors that generate the rate process, and whether the model is closed by equilibrium or arbitrage arguments.

Which of these models to use in OAS analysis depends on the available resources. Where resource availability is not an issue, we favor models that account for the path-dependent nature of mortgage cash flows. Good rules-of-thumb in deciding which model to use are as follows:

- *Flexibility*: How flexible is the model?
- *Simplicity*: Is the model easy to understand?
- *Specification*: Is the specification of the interest rate process reasonable?
- *Realism*: How real is the model?
- *Good fit*: How well does the result fit the market data?

- *Internal consistency rule*: A necessary condition for the existence of market equilibrium is the absence of arbitrage, and the external consistency rule requires models to be calibrated to market data.

TERM STRUCTURE MODELS: WHICH IS THE RIGHT APPROACH FOR OAS?

Numerical schemes are constructive or algorithmic methods for obtaining practical solutions to mathematical problems. They provide methods for effectively finding practical solutions to asset pricing PDEs.

The first issue in a numerical approach is discretization. The main objective for discretizing a problem is to reduce it from continuous parameters formulation to an equivalent discrete parameterization in a way that makes it amenable to practical solution. In financial valuation, one generally speaks of a continuous time process in an attempt to find an analytical solution to a problem; however, nearly all the practical solutions are garnered by discretizing space and time. Discretization involves finding numerical approximations to the solution at some given points rather than on a continuous domain.

Numerical approximation may involve the use of a pattern, lattice, network, or mesh of discrete points in place of the (continuous) whole domain, so that only approximate solutions are obtained for the domain in the isolated points, and other values such as integrals and derivatives can be obtained from the discrete solution by the means of interpolation and extrapolation.

With the discretization of the continuous domain come the issues of adequacy, accuracy, convergence, and stability. Perhaps how these issues are faithfully addressed in the implementation of OAS models speaks directly to the type of results achieved. Although these numerical

techniques—lattice methods, finite difference methods, and Monte Carlo methods—have been used to solve asset pricing PDEs, the lattice and Monte Carlo methods are more in vogue in OAS implementations.

Lattice Method

The most popular numerical scheme used by financial modelers is the *lattice* (or *tree*) *method*. A lattice is a nonempty collection of vertices and edges that represent some prescribed mathematical structures or properties. The node (vertex) of the lattice carries particular information about the evolution of a process that generates the lattice up to that point. An edge connects the vertices of a lattice. A lattice is initialized at its root, and the root is the primal node that records the beginning history of the process.

The lattice model works in a discrete framework and calculates expected values on a discrete space of paths. A node in a given path of a nonrecombining lattice distinguishes not only the value of the underlying claim there but also the history of the path up to the node. A bushy tree represents every path in the state space and can numerically value path-dependent claims. A node in a given path of a bushy tree distinguishes not only the value of the underlying claim there but also the history of the path to the node. There is a great cost in constructing a bushy tree model. For example, modeling a 10-year Treasury rate in a binary bushy tree with each time period equal to one coupon payment would require a tree with 2^{20} (1,048,576) paths. Figure 3 shows a schematic of a bushy tree.

In a lattice construction, it is usually assumed the time to maturity of the security, T , can be divided into discrete (finite and equal) time-steps M , $\Delta t = T/M$. The price of the underlying security is assumed to have a finite number of “jumps” (or up-and-down movements) N between the time-steps Δt . In a recombining lattice, the price or yield of the underlying security is assumed to be affected by N and not

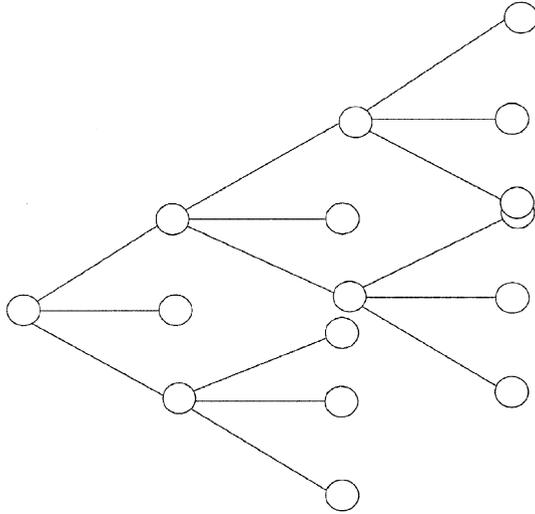

Figure 3 Bushy or Nonrecombining Tree

the sequences of the jumps. For computational ease, N is usually set to be two or three; the case where $N = 2$ is called binomial lattice (or tree), and $N = 3$ is the trinomial lattice. Figures 4 and 5 show the binomial and trinomial lattices, respectively, for the price of a zero-coupon bond.

Monte Carlo Method

The *Monte Carlo method* is a numerical scheme for solving mathematical models that involve random sampling. This scheme has been used to solve problems that are either deterministic or probabilistic in nature. In the most common

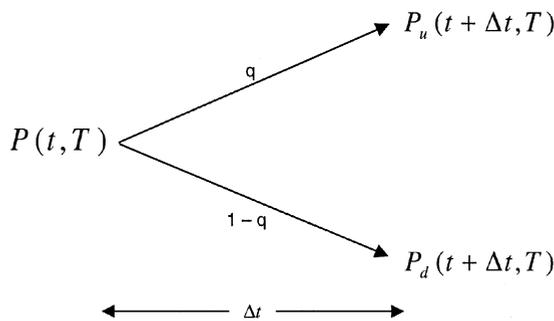

Figure 4 Binomial Lattice for the Price of a Zero-Coupon Bond

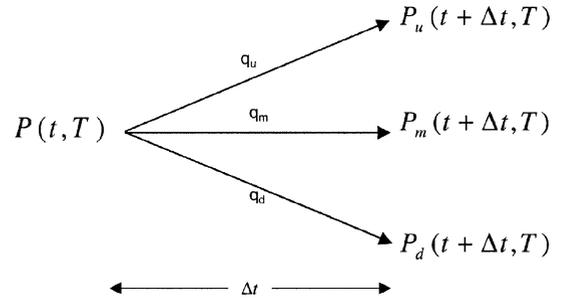

Figure 5 Trinomial Lattice for the Price of a Zero-Coupon Bond

application, the Monte Carlo method uses random or pseudo-random numbers to simulate random variables. Although the Monte Carlo method provides flexibilities in dealing with a probabilistic problem, it is not precise especially when one desires the highest level of accuracy at a reasonable cost and time.

Aside from this drawback, the Monte Carlo method has been shown to offer the following advantages:

- It is useful in dealing with multidimensional problems and boundary value problems with complicated boundaries.
- Problems with random coefficients, random boundary values, and stochastic parameters can be solved.
- Solving problems with discontinuous boundary functions, nonsmooth boundaries, and complicated right-hand sides of equations can be achieved.

The application of the Monte Carlo method in computational finance is predicated on the integral representation of security prices. The approach taken consists of the following:

- Simulating in a manner consistent with a risk-neutral probability (equivalent martingale) measure the sample path of the underlying state variables
- Evaluating the discounted payoff of the security on each sample path
- Taking the expected value of the discounted payoff over the entire sample paths

The Monte Carlo method computes a multidimensional integral—the expected value of discounted cash flows over the space of sample paths. For example, let $f(x)$ be an integral function over d -dimensional unit hypercube, then a simple (or crude) estimate of the integral is equal to the average value of the function f over n points selected at random (more appropriately, pseudorandom) from the unit hypercube. By the law of large numbers,²² the Monte Carlo estimate converges to the value as n tends to infinity. Moreover, we know from the central limit theorem that the standard error of estimate tends toward zero as $1/(\sqrt{n})$. To improve on the computational efficiency of the crude Monte Carlo method, there are several variance-reduction techniques available.

IS THERE A RIGHT WAY TO MODEL PREPAYMENTS?

Because cash flows are one of the most important inputs in determining the value of a security, there has to be a model for cash flow. The cash flow model consists of a model for distributing the coupon and scheduled principal payments to the bondholders, as contained in the deal prospectus, and a *prepayment model* that projects unscheduled principal payments. The basic types of prepayment models are as follows:

- *Rational prepayment models.* These models apply an option-theoretic approach and link prepayment and valuation in a single unified framework.
- *Econometric prepayment models.* This class of models is based on econometric and statistical analysis.
- *Reduced-form prepayment models.* This type of model uses past prepayment rates and other endogenous variables to explain current prepayment. It fits the observed prepayment data, unrestricted by theoretical consideration.

The reduced-form prepayment model is the most widely used approach among dealers and prepayment vendors because of its flexibility and unrestricted calibration techniques. The basic determinants of the voluntary and involuntary components of total prepayments are collateral and market factors. Collateral factors are the origination date, weighted average coupon (WAC), and weighted average maturity, and the market-related factors are benchmark rates and spreads.

KEY POINTS

- There are foundational issues that explain (1) why there is a difference in dealers' OAS values for a specific bond, (2) what may be responsible for the differences, and (3) why one OAS value may be more correct than another.
- As a general guideline, portfolio managers should become familiar with the economic intuitions and basic assumptions made by the models.
- The reasonableness of the OAS values produced by different models should be considered. Moreover, because prepayment options are not traded in the market, calibrating OAS values using the prices of these options is not possible.
- Interest rate models, which are closed by precluding arbitrage opportunities, are more tractable and realistic.
- Interest rate models that account for the path-dependent natures of ABS and MBS cash flows are more robust.
- With the path-dependent natures of ABS and MBS cash flows come the difficulties of implementation, in particular, the speed of calculation; the toss-up here is between the lattice and Monte Carlo schemes.
- There is a tendency for market participants to believe that because we are talking about interest rate scenarios, the ideal candidate for the job would be Monte Carlo techniques, but this should not necessarily be the case. Although lattice implementation could do a

good job, the success of this scheme depends highly on ad hoc techniques that have not been time-tested. Hence, whereas the OAS implementation scheme is at the crux of what distinguishes good or bad results, the preferred scheme is an open question that critically depends on available resources.

- Reduced-form prepayment models should be favored because of their flexibility and unrestricted calibration techniques. In particular, a model that explicitly identifies its control parameters and is amenable to the perturbation of these parameters is more robust and transparent.
- With respect to how to interpret the differences in dealers' OAS value for a specific security, decisions by dealers, vendors, and portfolio managers to choose one interest rate and prepayment model over others and the different approaches they take in implementing these models largely account for the wide variance in OAS results. Moreover, to complicate the issue, the lack of a market for tradable prepayment options makes calibrating the resulting OAS values dicey at best.
- As for whether there is a correct OAS value for a given security, examining the change in OAS value over time, the sensitivity of OAS parameters, and their implications to relative value analysis are some of the important indicators of the reasonableness of the OAS value.

NOTES

1. In the world of certainty, the present value is

$$PV = \sum_{i=1}^n \frac{cf_i}{(1+r_i)^i}$$

where r_i is the spot rate applicable to cash flow cf_i . In terms of forward rates, the equation becomes

$$PV = \sum_{i=1}^n \frac{cf_i}{(1+f_1)(1+f_2)\dots(1+f_n)}$$

where f_i is the forward rate applicable to cash flow cf_i .

2. The present value formula becomes more complicated and could be represented as

$$PV_{\Omega} = \sum_{\omega_i} \sum_{t_i}^T \frac{cf(t_i, \omega_i)}{(1+r(t_i, \omega_i))}$$

$$\forall i = 1, 2, \dots, N$$

where

PV_{Ω} = the present value of uncertain cash flow

$cf(t_i, \omega_i)$ = the cash flow received at time t_i and state ω_i

$r(t_i, \omega_i)$ = the spot rate applicable at time t_i and state ω_i

For OAS analysis, a stylized version of the previous equation is given by

$$PV_{\Omega} = \lim_{n \rightarrow \infty} \frac{1}{N} \frac{cf(t_i, \omega_i)}{(1+r(t_i, \omega_i))}$$

$$\forall i = 1, 2, \dots, N$$

3. $\$1 \left[\exp \left(\int_t^T r(u) du \right) \right]$
4. $p(t, T) = E \left[\exp \left(- \int_t^T r(u, du) \middle| F_t \right) \right]$
5. Cox, Ingersoll, and Ross (1985).
6. Black and Scholes (1973).
7. Merton (1974).
8. Hull and White (1990).
9. Black, Derman, and Toy (1990).
10. Heath, Jarrow, and Morton (1992).
11. For example, the PDE for a zero-coupon bond price is

$$\frac{\partial p}{\partial t} + \frac{1}{2} \sigma^2 \frac{\partial^2 p}{\partial r^2} + (\mu - \lambda \sigma) \frac{\partial p}{\partial r} - rp = 0$$

where

p = zero-coupon price

r = instantaneous risk-free rate

μ = the drift rate

σ = volatility

λ = market price of risk

To solve the zero-coupon price PDE, we must state the final and boundary

conditions. The final condition that corresponds to payoff at maturity is $p(r, T) = k$.

12. The bank account is denoted by

$$B(t) = \exp \left[\int_0^t r(u) du \right]$$

and $B(0) = 1$.

13. Technically, the term structure model is said to be arbitrage-free if and only if there is a probability measure \mathbf{Q} on Ω ($\mathbf{Q} \sim \mathbf{P}$) with the same null

$$Z(t, T) = \frac{P(t, T)}{B(t)}, 0 \leq t \leq T$$

set as \mathbf{P} , such that for each t , the process is a martingale under \mathbf{Q} .

14. State space is the space in which the possible values of X_t lie. Let S be the state space. If $S = (0, 1, 2, \dots)$, the process is called the discrete state process. If $S = \mathfrak{R}(-\infty, \infty)$ that is the real line, and the process is called the real-valued stochastic process. If S is Euclidean d -space, then the process is called the d -dimensional process.
15. Index parameter: If $T = (0, 1, \dots)$, then X_t is called the discrete-time stochastic process. If $T = \mathfrak{R}_+[0, \infty)$, then X_t is called a continuous time stochastic process.
16. Formally, a stochastic process is a family of random variables $X = \{x_t; t \in T\}$, where T is an ordered subset of the positive real line \mathfrak{R}_+ . A stochastic process X with a time set $[0, T]$ can be viewed as a mapping from $\Omega \times [0, T]$ to \mathfrak{R} with $x(\omega, t)$ denoting the value of the process at time t and state ω . For each $\omega \in \Omega$, $\{x(\omega, t); t \in [0, T]\}$ is a sample path of X sometimes denoted as $x(\omega, \bullet)$. A stochastic process $X = \{x_t; t \in [0, T]\}$ is said to be adapted to filtration F if x_t is measurable with respect to F_t for all $t \in [0, T]$. The adaptedness of a process is an informational constraint: The value of the process at any time t cannot depend on the information yet to be revealed strictly after t .
17. A process X is said to have an independent increment if the random variables $x(t_1) -$

$x(t_0), x(t_2) - x(t_1) \dots$ and $x(t_n) - x(t_{n-1})$ are independent for any $n \geq 1$ and $0 \leq t_0 < t_1 < \dots < t_n \leq T$. A process X is said to have a stationary independent increment if, moreover, the distribution of $x(t) - x(s)$ depends only on $t - s$. We write $z \sim N(\mu, \sigma^2)$ to mean the random variable z has normal distribution with mean μ and variance σ^2 . A standard Brownian motion W is a process having continuous sample paths, stationary independent increments, and $W(t) \sim N(\mu, t)$ (under probability measure P). Note that if X is a continuous process with stationary and independent increments, then X is a Brownian motion. A strong Markov property is a memoryless property of a Brownian motion. Given X as a Markov process, the past and future are statistically independent when the present is known.

18. We write

$$E_t[R_t] = E[R_T | F_t], t < T$$

19. More concretely, given a probability space, a process $\{R_t; t \in (0, \infty)\}$ is a martingale with respect to information sets F_t , if for all $t > 0$,
1. R_t is known, given F_t , that is, R_t is F_t adapted
 2. Unconditional forecast is finite; $E|R_t| < \infty$
 3. And if

$$E_t[R_t] = R_T, \quad \forall t < T$$

with a probability of 1. The best forecast of unobserved future value is the last observation on R_t .

20. In particular, assume

$$dX(t) = \alpha(t, X(t))dt + \beta(t, X(t))dW(t)$$

for which the solution $X(t)$ is the factor. Depending on the application, one can have n -factors, in which case we let X be an n -dimensional process and W an n -dimensional Brownian motion. Assume the stochastic differential equation for $X(t)$ describes the interest process $r(t)$, (i.e., $r(t)$

is a function of $X(t)$. A one-factor model of interest rate is

$$dr(t) = \alpha(t)dt + \beta(t)dW(t)$$

21. This process is represented as

$$dr = a(b - r)dt + \sigma r^\beta dW$$

where a and b are called the reversion speed and level, respectively.

22. *Strong Law of Large Numbers*. Let $X = X_1, X_2 \dots$ be an independent identically distributed random variable with $E(X^2) < \infty$ then the mean of the sequence up to the n th term, though itself a random variable, tends as n get larger and larger, to the expectation of X with probability 1. That is

$$P\left(\lim_{n \rightarrow \infty} \left(\frac{1}{n} \sum_{i=1}^n X_i\right) = E(X)\right) = 1$$

Quantitative Models to Value Convertible Bonds

FILIPPO STEFANINI

Head of Hedge Funds and Manager Selection, Eurizon Capital SGR

Abstract: Convertible bonds are bonds that give their holders the right to periodic coupon payments and, as of a fixed date, the right to convert the bonds into a fixed number of shares. If the bondholder decides to exercise his conversion right, instead of being paid back the par value of the bonds, he will receive a fixed number of shares in exchange. There are several options embedded in a convertible bond. There is obviously a call option on the underlying stock. All convertible bonds are callable. A convertible bond may be puttable. The presence of all of these options complicates the valuation of convertible bonds. There are models that practitioners use for valuation purposes. These models are classified as analytical models and numerical models.

Convertibles are ideal securities for arbitrage, because the convertible itself, namely the underlying stock and the associated derivatives, are traded along predictable ratios, and any discrepancy or misprice would give rise to arbitrage opportunities for fund managers. Traders use quantitative models to identify convertible bonds whose market value differs from their theoretical price. However, unlike callable bonds or puttable bonds that have interest rate-embedded options, a convertible bond also has an embedded equity option. This complicates the quantitative modeling of these securities.

Quantitative models, or valuation models, for convertible bonds are divided into two categories: *analytical models* and *numerical models*. In this entry, we describe the more commonly used model in both of these categories.

ANALYTICAL MODELS

Ingersoll (1977) proposed a valuation model for convertible bonds based on the option theory and on the Black-Scholes option pricing model. The model's main assumptions are:

- Markets operate continuously.
- There are no transaction costs.
- Share prices follow an Ito diffusion process.
- Securities prices have a lognormal distribution.
- The underlying stock volatility is constant.

Ingersoll's model assumes that prices vary continuously, that is, there is always liquidity in the market and there are no limits to securities lending and short selling. It also assumes that the company's market value follows an Ito diffusion process, that is, a continuous Brownian

motion. Under this assumption, it is possible to set up a closed analytical formula to calculate the value of a convertible bond.

The model can be applied only to European convertibles, namely, convertibles that can be exercised only upon expiration. Moreover, the model makes it clear how complex the valuation of convertible bonds is, and it provides a highly interesting theoretical reference, in that it can reach an analytical solution to the valuation of convertibles. Yet, we know all too well that interest rates, credit spreads, currencies, and dividends are not constant, and the clauses and provisions written in the prospectus of a convertible are often highly varied and complicated, making it fairly difficult to apply analytical valuation models. This is why it is necessary to turn to numerical approximation models.

The Ingersoll Model

As just noted, the *Ingersoll model* provides an analytic solution for the pricing of a convertible bond, given some general market assumptions. The strongest assumptions are:

- Capital markets are perfect with no transaction costs, no taxes, and equal access to information for all investors.
- Trading takes place continuously in time and there are no restrictions against borrowing or short sales.
- The market value of the company follows an Ito diffusion process.

The Black-Scholes option pricing model is used to value the convertible bond as a contingent claim on the firm as a whole.

Consider a convertible bond that is convertible only at maturity, therefore with a European call option embedded. Let

$$\gamma = \frac{n}{n + N}$$

equal the dilution factor, indicating the fraction of the common equity that would be held by

the convertible bond issue's owners if the entire issue were converted:

- V = market value of the company
- τ = maturity of the convertible bond
- B = balloon payment (nominal value of the convertible bond)
- r = interest rate

In light of the continuous-time analysis, the functional form to assume for the call price of a convertible bond is the exponential:

$$K(\tau) = B \cdot e^{-\rho\tau}$$

where

- ρ = rate of change in the call price
- σ^2 = the instantaneous variance of returns of the stock underlying the convertible bond

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-t^2/2} dt$$

is the cumulative normal distribution

$$F(V, \tau; B, 0) = B \cdot e^{-r\tau} \cdot \left[\Phi \left(\frac{-\log(B \cdot e^{-r\tau}/V) + \frac{1}{2}\sigma^2\tau}{\sigma\sqrt{\tau}} \right) + V \cdot \Phi \left(\frac{-\frac{\log(B \cdot e^{-r\tau}/V) + \frac{1}{2}\sigma^2\tau}{\sigma\sqrt{\tau}}}{\frac{B \cdot e^{-r\tau}}{V}} \right) \right]$$

$$W(\gamma V, \tau; B) = \gamma \cdot V \cdot \Phi \left(\frac{\log(\frac{\gamma V}{B}) + (r + \frac{1}{2}\sigma^2)\tau}{\sigma\sqrt{\tau}} \right) - B \cdot e^{-r\tau} \cdot \Phi \left(\frac{\log(\frac{\gamma V}{B}) + (r + \frac{1}{2}\sigma^2)\tau}{\sigma\sqrt{\tau}} - \sigma\sqrt{\tau} \right)$$

The value of the convertible bond is

$$H(V, \tau) = F(V, \tau; B, 0) + W(\gamma V, \tau; B) + \left(\frac{K(\tau)}{\gamma V} \right)^{2(r-\rho)/\sigma^2} \cdot \left(F(\gamma V \cdot e^{(\rho-r)\tau}, \tau; B \cdot e^{(r-\rho)\tau}, 0) - F(\gamma V \cdot e^{(\rho-r)\tau}, \tau; \frac{B}{\gamma} \cdot e^{(r-\rho)\tau}, 0) \right)$$

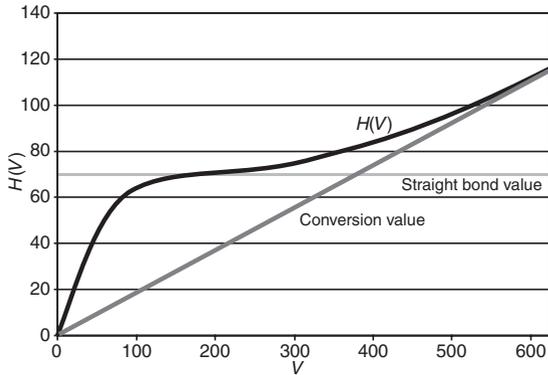

Figure 1 Plot of a Convertible Bond Function for Different Firm Values

To illustrate the model, let's plot the function H with the following parameters:

- $B = 100$
- $\rho = 0,02$
- $\gamma = 0,2$
- $\sigma^2 = 5\%$
- $r = 7\%$

V ranges from 0 to 625.

The plots are shown in Figure 1. The straight lines cross at

$$V(\tau) = \frac{K(\tau)}{\gamma}$$

NUMERICAL MODELS

The most widely used mathematical models among hedge fund managers for the valuation of convertible bonds are numerical methods, among which are the binomial and trinomial trees, the three-dimensional binomial model, implied trees, and the Monte Carlo simulation model.

The *binomial tree model* was introduced by Cox, Ross, and Rubinstein (1979) and by Sharpe in his textbook (Sharpe, 1978). This model allows one to build a tree of possible share prices between now and the convertible's maturity date. This tree is then used to find the convertible's current value by calculating its value along all the tree's nodes. In the binomial tree model,

the tree has two branches that develop from every node, while in the trinomial tree model there are three branches diverging from each node. The higher the number of nodes, the more accurate the model is. The binomial model makes it possible to also value an American option that would otherwise find no solution in a closed form. If the number of time steps grows bigger, the binomial tree tends toward the Black-Scholes continuous formula for European options.

All these models are helpful when making a decision, but many of the options embedded in a convertible do not fit the models and therefore the fund manager's skill and a rigorous risk management discipline become more precious. The manager's art lies in finding innovative ways to evaluate convertible bonds without being swamped with too many details.

The trinomial tree model was introduced by Boyle (1986). The share price can move in three directions from every single node and therefore the number of time steps can be reduced to reach the same precision obtained with the binomial tree.

The *Monte Carlo method*, named after the casino of the Principality of Monaco, is a statistical simulation method, according to which data obtained through the generation of random numbers coming from a given statistical distribution is considered empirical and is used to estimate the parameters under consideration. Thousands of random samples are generated, derived from the assumed statistical distribution, which takes as parameters the maximum likelihood estimators using real data, and then these data are used to estimate the parameters under examination.

The Binomial Tree Model

Here, we will describe a version of the Cox-Ross-Rubinstein model as modified by Goldman Sachs. The binomial tree model can be used to evaluate convertible bonds with either an

embedded European call option or an embedded American call option.

To determine the value of the convertible bond, it's necessary to build four different trees in the following order:

1. Stock price tree.
2. Conversion probability tree.
3. Credit-adjusted spread tree.
4. Convertible bond value tree that is calculated backward from the previous trees.

In the first step we build the stock price tree. The binomial tree model allows us to build up a picture of how a stock is likely to perform between now and the maturity of the convertible bond (T). The number of nodes (N) is calculated from the maturity of the convertible bond according to the formula $T \cdot (T + 1)/2$. The more nodes, the more accurate will be the model.

Between a node and the following node, the stock price can move upward or downward. The jump of the stock price depends on the length of the time interval $\Delta t = T/N$ and on the stock price volatility σ . Therefore

$$\begin{aligned} u &= e^{\sigma\sqrt{\Delta t}} \text{ (upward move)} \\ d &= e^{-\sigma\sqrt{\Delta t}} \text{ (downward move)} \end{aligned}$$

The stock price, S , at each node is set equal to

$$S \cdot u^i \cdot d^{j-i}$$

where $i = 0, 1, \dots, j$

N is the time step and i is the number of upward moves.

The probability of a downward move in stock price at the next time step Δt is

$$p = \frac{e^{b\sqrt{\Delta t}-d}}{u-d}$$

while the probability of a downward move must be $(1 - p)$, since the probability of going either up or down equals unity.

In the second step we build the conversion probability tree. We calculate the conversion probabilities backward, starting from the leaves of the stock price tree. If it's optimal to convert the bond, the conversion probability is 1, other-

wise it is 0. For the steps before the end of the tree, the conversion probability is 1 if it's optimal to convert the bond; otherwise, it is equal to

$$q_{n,i} = p \cdot q_{n+1,i+1} + (1 + p) \cdot q_{n+1,i}$$

In the third step we build the credit-adjusted spread tree. If the convertible bond is out-of-the-money, futures cash flows should be discounted to a rate equal to the risk-free rate, r , plus a credit spread, k , of that particular bond. In fact, if the stock price is much lower than the conversion price, the convertible bond behaves like a plain vanilla bond. If the convertible bond is in-the-money, future cash flows must be discounted at the risk-free rate. In this case, the convertible bond behaves like a stock. Therefore, instead of using a fixed discount rate r , in each node is calculated a discount rate $r_{n,i}$ and a conversion probability $q_{n,i}$ is used. The discount rate is equal to

$$r_{n,i} = q_{n,i} \cdot r + (1 - q_{n,i}) \cdot (r + k)$$

In the fourth step, we build the convertible bond value tree. At each node of the tree, the price of the convertible bond is equal to the maximum between the conversion value of the bond and the face value plus the final coupon. The tree is built backward: from the leaves back to the root of the tree. The root of the tree is the price of the convertible bond.

If it's optimal to convert the bond at a node, then that node is assigned the conversion value; otherwise, the price of the convertible bond is

$$\begin{aligned} P_{n,i} &= \max[mS, p \cdot P_{n+1,i+1} \cdot e^{r_{n+1,i+1} \cdot \Delta t} \\ &\quad + (1 - p) \cdot P_{n+1,i} \cdot e^{-r_{n+1,i} \cdot \Delta t}] \end{aligned}$$

where m is the conversion ratio.

For example, let's determine the price of a convertible bond with the binomial tree method, starting with the following data:

- $T = 5$ years (maturity)
- $\Delta t = 1$ year (step)
- $N = 5$ (number of nodes)
- $r = 4\%$ (risk-free rate)
- $k = 2\%$ (credit spread)

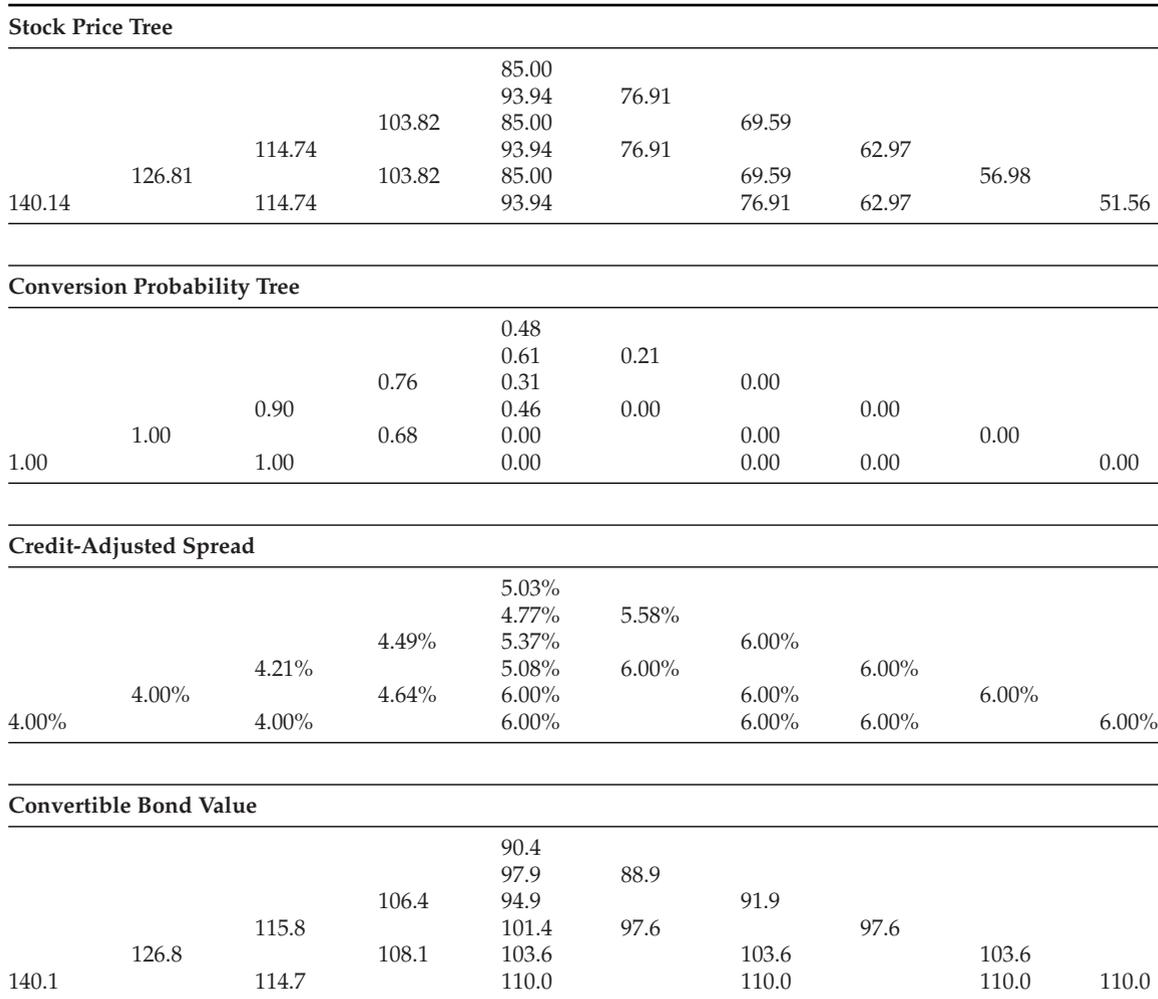

Figure 2 Binomial Trees Necessary to Determine the Value of a Convertible Bond

The convertible bond has nominal value 100 and coupon 10%.

$m = 100\%$ (conversion ratio)

$S = 85$ (stock price)

$\sigma = 10\%$ (stock volatility)

With the formulas discussed above we calculate

$u = 1.1052$ (upwards move)

$d = 0.9048$ (downwards move)

$p = 0.6787$ (probability of an upward move of the stock price in the next time interval Δt)

As shown in Figure 2 we built first the stock price tree, then the conversion probability tree,

then the credit-adjusted spread tree, and finally the convertible bond value tree. The value in the root of the tree is 90.4, which is the price of the convertible bond.

KEY POINTS

- To implement strategies involving convertible bonds, traders and fund managers require a valuation model.
- Analytical models provide a closed-form solution for the value of a convertible bond, and the most commonly used model in practice is the Ingersoll model.

- While there are several models that fall into the realm of numerical models, the one commonly used is the binomial tree model, which requires the construction of a stock price tree, conversion probability tree, credit-adjusted spread tree, and convertible bond value tree that is calculated backward from the previous trees.

Quantitative Approaches to Inflation-Indexed Bonds

WESLEY PHOA, PhD

Senior Vice President, Capital International Research, Inc.

Abstract: Inflation-indexed bonds, as a way of financing government debt, were proposed in the 1920s by economists such as Alfred Marshall and John Maynard Keynes. In Israel, they have been issued since the 1950s and have often dominated that country's bond market. Inflation-indexed sovereign bonds now exist in a broad range of developed countries, as well as in a number of emerging markets. A wide variety of bond structures and tax regimes exist. Issuance volumes and the breadth of the investor base vary widely from country to country; liquidity varies from reasonably good to very poor. When inflation-indexed bonds were introduced in the United States in 1997, there was some disagreement about the degree to which inflation-indexed bonds—called Treasury inflation-protected securities or TIPS—are “risk-free” and the role they should play in a portfolio. In particular, it had not been universally appreciated that these bonds can have volatile mark-to-market returns.

Since their introduction in 1997, *Treasury inflation-protected securities (TIPS)* have become an established part of the U.S. bond market. This entry reviews the structure of TIPS and the factors that drive TIPS returns; examines the role that TIPS play in a broader bond portfolio, and the nature of TIPS interest rate risk; and discusses some methods employed by TIPS investors to assess value and risk.

BOND STRUCTURES AND THE CONCEPT OF REAL YIELD

The key features of the TIPS bond structure are summarized here:

- TIPS pay interest semiannually. Interest payments are based on a fixed coupon rate. However, the underlying principal amount of the bonds is indexed to inflation; this inflation-adjusted principal amount is used to calculate the coupon payments, which therefore also rise with inflation. At maturity, the redemption value of the bonds is equal to their inflation-adjusted principal amount, rather than their original par amount.
- The inflation-adjusted principal amount is equal to the original par amount multiplied by an index ratio, which is based on changes in the *Consumer Price Index (CPI)* and which is recalculated every day. The index ratio is simply the reference CPI on the relevant date divided by the reference CPI on the

issue date. Negative inflation adjustments are not made.

- The reference CPI for the first day of any month is defined to be the non-seasonally adjusted CPI-U for the third preceding calendar month, while the reference CPI for any subsequent day in that month is determined by linearly interpolating the reference CPI for the first of the month and the reference CPI for the first day of the next month.
- Price-yield calculations are as follows. Compute the “real price” of the bond from the quoted *real yield* via the standard bond pricing formula, using an actual/actual day count basis, round to 3 decimal places (in \$100); then multiply the real price by the index ratio to obtain the inflation-adjusted price. Accrued interest is computed in exactly the same way, except that no rounding is carried out.

An attractive feature of the TIPS structure is that inflation indexation occurs with no substantial lag. In the U.K., there is an eight-month lag in the inflation adjustment of index-linked gilts; in Australia and New Zealand, there is a three- to six-month lag. The lag means that real returns from these *inflation-indexed bonds* are subject to short-term inflation risk and considerably complicates the analysis of the bonds.

The obvious question, of course, is: Where does the real yield come from, and how much can it change? To investors used to thinking of bond yields as being driven by inflation expectations, it is not obvious that real yields should be volatile at all—except perhaps because of temporary imbalances in supply and demand, or changes in liquidity. After all, there are respectable economic theories that suggest that real interest rates should be constant. But in practice, there are various economic reasons why real yields do in fact fluctuate.¹

Causes of Real Yield Volatility

The real yield may be defined as the long-term cost of risk-free capital (net of inflation). That

is, since TIPS are competing with other investments, real yields on TIPS will move with the cost of capital in the economy as a whole. Of course, other factors affect real yields: For example, index-linked gilts in the U.K. have had artificially low real yields because of their favorable tax treatment and because of a regulatory requirement (since loosened) making it virtually obligatory for pension funds to own them. However, in this entry we will focus on economic and market factors.

Long-term real yields are influenced by expectations about future long-term real interest rates. The two main macroeconomic factors that affect these expectations are:

1. The *domestic* factor: long-term expected growth in real gross domestic product (GDP). Strong growth generally drives up real interest rates, since the demand for capital tends to rise, and borrowers—expecting higher real returns—are prepared to shoulder higher real borrowing costs.
2. The *international* factor: long-term expected changes in the current account deficit. Demand for capital is by definition higher in countries with a large current account deficit, driving up domestic interest rates in order to attract required international investment.

Note that short-term trends in real GDP and the current account deficit can have a strong influence on real yields, because they tend to influence the long-term expectations of investors.² (Roll [1996] has also argued, based on an analysis of tax effects, that real yields should also rise when expected inflation rises; this argument is outlined later in this entry. For the moment we ignore tax effects.)

Real yields on inflation-linked bonds are also influenced by relative demand for these bonds when compared with competing investments that may offer investors some protection—albeit imperfect—against inflation. The balance between competing investments constantly shifts, depending on subjective

factors such as investor aversion to different kinds of risk. Relevant investments include:

1. *Money market investments*: If investors are confident that short-term interest rates will move broadly in line with inflation—which was the case for US monetary policy during the “Great Moderation” period from the early 1980s up to the recent financial crisis, but not before or since—then real returns on money market instruments will be relatively stable over the long term.
2. *Equities*: When profit margins are stable, corporate profits, and hence dividends and dividend growth rates, tend to rise with the price level; thus, it is reasonable to regard equities as an inflation hedge in the long term (remembering that equity investors are exposed to additional risks in comparison to holders of inflation-indexed bonds).
3. *Corporate bonds*: As with equities, corporate bond performance is partly linked to inflation: Rising price levels drive up corporate revenues and reduce the real value of existing fixed-rate debt, and both these factors can cause yield spreads to tighten. However, this relationship is often weak and dominated by other factors.
4. *Commodities*: A basket of commodities also provides a partial hedge against inflation; in practice, this investment alternative was not historically as important as the previous three, though its importance has increased considerably since 2005 as financial innovation has expanded the investor base.

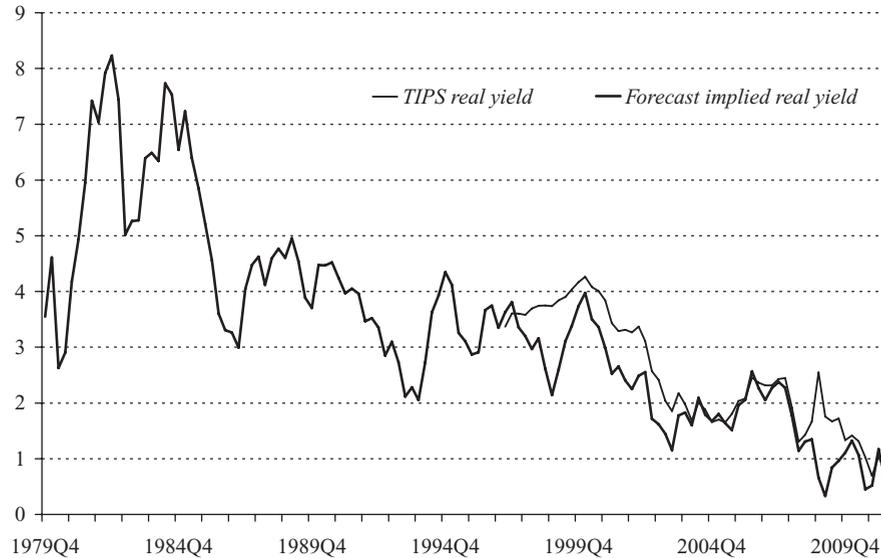

To summarize: Real yields are far from stable, and the behavior of real yields is just as complex as the behavior of nominal yields. Real yields are influenced by both economic fundamentals and market supply/demand factors across asset classes. It is not at all obvious that inflation-linked bonds should be “among the least risky of all assets.” Indeed, in the Australian market these securities were long regarded as highly risky in comparison to nominal bonds—though this is partly because of their poorer liquidity.

In all countries where inflation-linked bonds are actively traded, real yields have, historically, been quite volatile. Like nominal yields, market real yields trade in ranges of hundreds of basis points (see Figure 1). Historical examples from other countries include:

- In the U.K., real yields on long index-linked gilts fluctuated between 2% and 4.5% in the period 1981–1993.³ In the period 1984–1994, real yields on short index-linked gilts fluctuated between 1.5% and 5.75%, partly reflecting instability in monetary policy.⁴
- In Israel from 1984–1993, long-dated real yields fluctuated between –1.5% and 3.3%; however, they more typically traded in the range $\pm 1\%$.⁵
- In Australia, real yields have varied from a high of 5.75% in 1986 and 1994 to a low of 3.25% in 1993.⁶

Real yields are often estimated by subtracting current (i.e., recent historical) inflation from current nominal bond yields; but this procedure is obviously illogical, as it assumes that expected inflation is equal to current inflation. One can get a better idea of what market real yields would have been by taking nominal yields and subtracting a consensus inflation forecast. Figure 1 shows the 10-year nominal Treasury yield minus the 10-year consensus CPI forecast, as reported in the Philadelphia Fed’s Survey of Professional Forecasters; this measures investors’ expectations of real returns on 10-year Treasury bonds and is therefore a reasonable estimate of the 10-year real yield going back several decades. Figure 1 also shows the market real yield of the 10-year TIPS (dating back only to 1997); it is correlated with the survey-based real yield estimate, but not perfectly. We discuss this divergence at the end of the entry.

Even though using consensus data has a number of drawbacks, this rough analysis yields some useful results. The figure shows clearly how long-dated real yields soared in the early

Source: Bloomberg; Federal Reserve Board

Figure 1 U.S. 10-Year Real Yield Estimated from Consensus Long-Term CPI Forecasts and TIPS Real Yield

1980s, due to the extreme instability in monetary policy. They stabilized after 1985, once the Fed stopped targeting monetary aggregates and adopted interest rate targeting instead. Since then they have fluctuated between 5% (in the overheated economy of the late 1980s) and less than 0.5% (in the crisis and postcrisis periods). Note the apparent link between long-term real yields and current GDP growth in recent years.

Figure 2 shows a more detailed history of TIPS real yields since issuance. It also shows the yield spread between the 10-year TIPS and the 10-year CMT nominal yield. This may be regarded as a rough measure of the market's inflation expectations over the next 10 years.

It's interesting that 10-year TIPS real yields have never been stable, whereas 10-year TIPS break-even inflation was remarkably stable from about 2004–2007, a period of relative macroeconomic stability and strong Fed credibility. Also note the extraordinary period of volatility during the crisis period of late 2008 and early 2009, during which TIPS were highly correlated with risky asset classes such as equities and credit (as predicted above, but per-

haps not for the fundamental economic reasons cited).

A derivative market for inflation swaps has developed alongside the cash market for inflation-linked bonds. While inflation swaps will not be discussed explicitly in this entry, much of the material is also applicable to them.

Existence of an Inflation Risk Premium

It is often asserted that real yields on inflation-linked bonds should reflect an *inflation risk premium*, since investors are not exposed to inflation risk as they are with nominal bonds. Note that if future inflation were known—not necessarily zero—there would be no inflation risk premium; it is uncertainty about inflation that creates a risk premium. The more volatile inflation is expected to be, the higher the inflation risk premium on nominal bonds should be, and the lower real yields should be in relation to nominal yields.

It is important to note that it is uncertainty about future inflation that should determine the

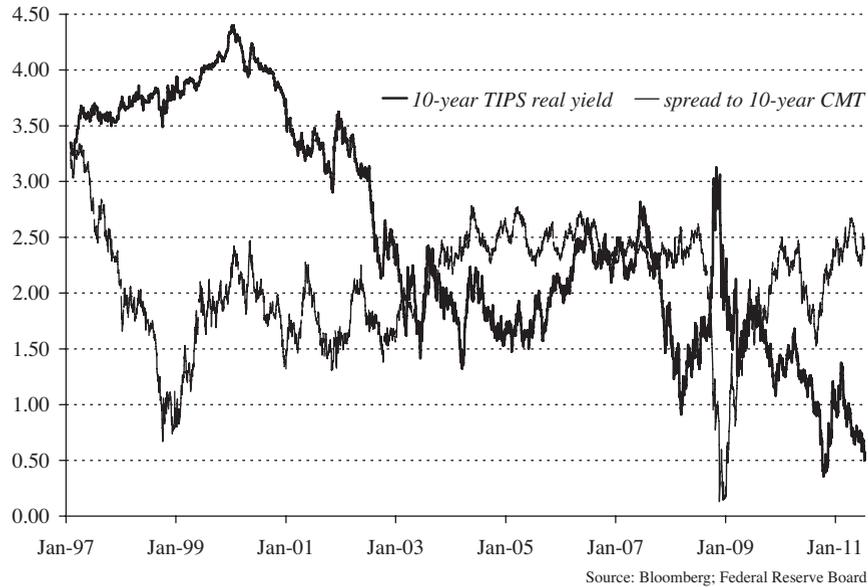

Figure 2 TIPS Real Yield History and Spread to Nominal Yield Curve (“Break-Even Inflation”)

risk premium, not the historical volatility of inflation. For example, the inflationary episode of the 1970s is not relevant unless investors think it may be repeated. Investors’ expectations about the future volatility of inflation are not directly observable, but it may be helpful to look at economists’ estimates. It is also useful to compare expected inflation volatility with expected volatility in real interest rates, since both factors are relevant to the risk/return opportunities offered by inflation-indexed bonds.

Note that if the inflation risk premium exists, one would not expect it to be unvarying. Since it is related to market expectations about potential uncertainty in inflation, it is comparable to option-implied volatility. One would thus expect the inflation risk premium to depend on bond maturity, and also to vary over time; for example, if the market lost confidence in the Fed’s ability or willingness to control inflation, the inflation risk premium would rise, causing nominal yields to rise relative to real yields. However, since the inflation risk premium is determined by inflation uncertainty over a long period (10 years for the

10-year TIPS), sudden changes should be unusual. Absent unusual shocks to Fed credibility, the inflation risk premium should experience moderate fluctuations, like long-dated swaption implied volatilities, and not sharp ones, like short-dated exchange-traded option implied volatilities.

In the absence of a complete inflation-linked derivatives market, the inflation risk premium is not directly observable. Furthermore, naive attempts to measure it can lead to grossly overstated estimates, and a number of proposed methods for measuring it turn out to be spurious. For example, it has been asserted that the differential between money market and bond yields arises because of an inflation risk premium, which can thus be estimated by looking at the long-term average spread between the Fed Funds rate and the two-year bond yield (about 70 bp in the period since deregulation). This argument has a grain of truth, but the conclusion is incorrect as it stands. The slope of the yield curve reflects a term premium that is not solely attributable to inflation risk. In addition, there are other reasons why money

market yields are usually lower than bond yields: Liquidity preference and the impact of capital charges both have important effects. Furthermore, if the spread between money market and bond yields reflects a risk premium, this is not just an inflation risk premium but a real rate risk premium as well.

Also, the argument that the difference between the Fed Funds rate and the two-year bond yield equals the inflation risk premium implies that the yields of money market securities reflect no inflation risk premium, while this risk premium is fully priced into two-year bond yields. This would only be plausible if money market securities were not (perceived to be) subject to inflation risk, and this is far from obvious, particularly since real money market returns were frequently negative during the 1970s.

Thus we must look for more valid ways of estimating what the inflation risk premium should be. There is no strong consensus in the literature, and a surprisingly wide range of estimates appears in the literature, from around 100 bp to modestly negative.⁷ However, the most credible estimates tend to fall in the zero to 50 bp range.⁸

One approach is to try to observe inflation uncertainty directly and then derive a “fair” inflation risk premium by applying a market price of risk. Figure 3 shows the probabilities attached by economists to various GDP growth and inflation scenarios; it is taken from the Survey of Professional Forecasters.

Economists’ forecasts recognize that both inflation and real yields are volatile, and that they have comparable volatilities. It is tempting to conclude that nominal bond yields should indeed reflect an inflation risk premium, since returns on nominal bonds are affected by both inflation volatility and real yield volatility, while returns on inflation-linked bonds are only affected by real yield volatility. And the reported uncertainty in inflation naively leads to an (again, very rough) estimate of the inflation risk premium at the upper end of the range

mentioned above. But this conclusion is not necessarily correct.

Based on an analysis of 30 years’ worth of cross-country panel data, Judson and Orphanides (1999) have shown that—as one might expect—there is a strong negative correlation between inflation and growth. Thus, as inflation rises, real yields should fall, and vice versa; in other words, the risks arising from fluctuations in inflation and fluctuations in real yields at least partly offset each other, at least over the medium to long term. It is therefore conceivable that, over the medium to long term, a portfolio of nominal bonds may be less risky, not more risky, than a portfolio of inflation-linked bonds, in which case an inflation risk premium need not exist at all. Certainly the situation is more complex than it seems at first.

We can actually use the earlier “economists’ estimates” of volatility in real GDP growth and CPI inflation, together with the implied volatility of short-term rates, to compute a rough estimate of the correlation between inflation and growth. Assuming that nominal rates are solely determined by growth and inflation, we have:

$$\sigma_{nom}^2 = \sigma_{GDP}^2 + \sigma_{CPI}^2 + 2\rho\sigma_{GDP}\sigma_{CPI}$$

where σ_{GDP} , σ_{CPI} denote the volatility of growth and inflation respectively, and ρ is the correlation between growth and inflation.

If all three volatilities are around 1% per annum, then solving this formula for ρ gives an estimate of around 0.5. However, it would not be meaningful to try to compute a more precise estimate this way.

Incidentally, Judson and Orphanides (1999) also found a strong negative correlation between inflation volatility and growth. In other words, if inflation is expected to become more volatile, real yields should fall, that is, inflation-indexed bond prices should rally. However, in this scenario inflation-linked bonds should outperform nominal bonds, since the inflation risk premium should rise.

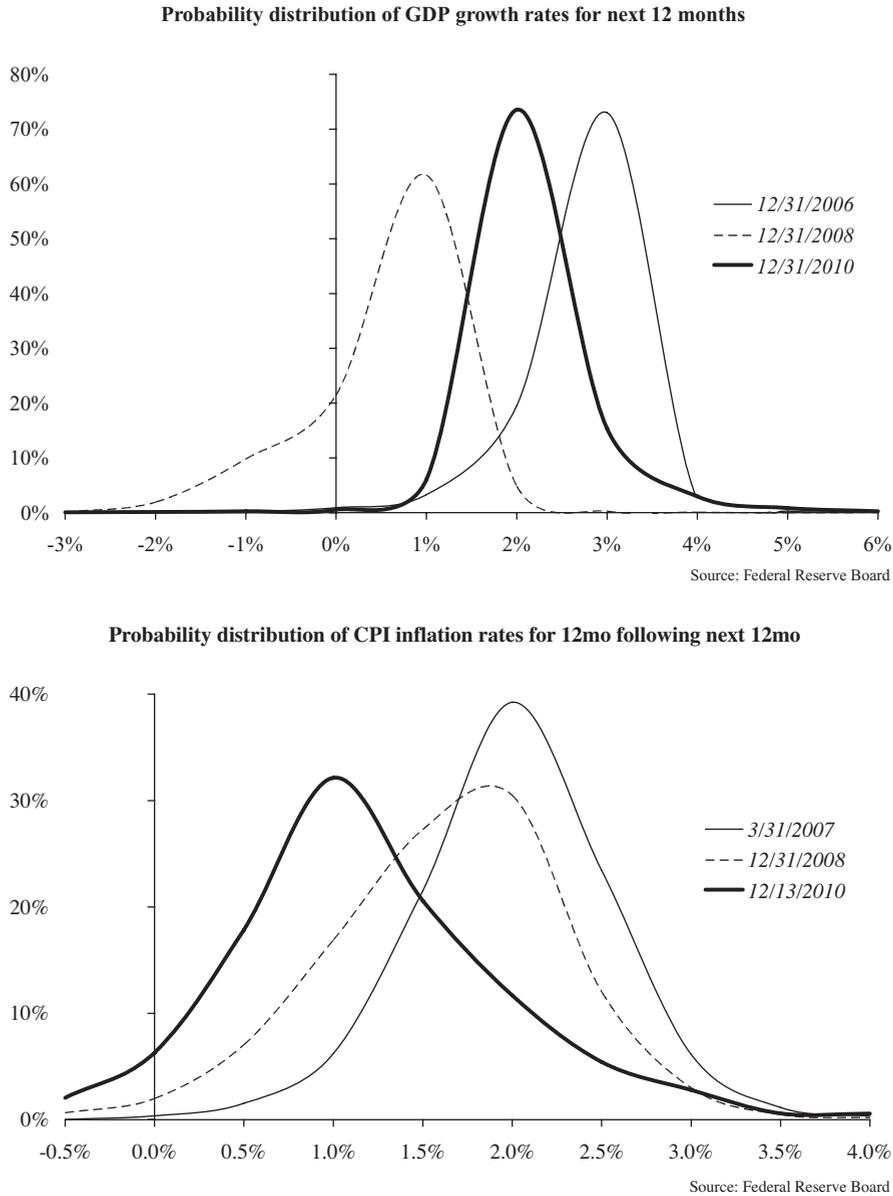

Figure 3 Economists' Uncertainty about Future GDP Growth and Future Inflation

INFLATION-INDEXED BONDS IN A NOMINAL PORTFOLIO

TIPS behave in unique ways and resemble neither nominal Treasuries nor spread products. It's therefore worth going back to basics in order to understand the nature of the interest rate

risk inherent in TIPS and the role they can play in broader portfolios.

What Is the Duration of an Inflation-Indexed Bond?

Inflation-indexed bonds are often used for specialized purposes (e.g., asset/liability

management for insurance companies offering inflation-linked life annuities, or for defined benefit plans where benefits are subject to cost of living adjustments), and may thus be segregated from other fixed-income holdings. However, if they are held in the same portfolio as nominal bonds, an interesting problem arises when attempting to define their price sensitivity to rate changes as measured by “duration.” We first examine the simplest possible definition of duration and its consequences; then we look at some alternative definitions.

It is easy to compute the duration of an inflation-indexed bond using exactly the same method as one would use for a nominal bond. Because of its low real coupon and low real yield, an inflation-indexed bond tends to have a much longer duration than a nominal bond of comparable maturity.

But what does this duration mean? The duration of a nominal Treasury bond measures its sensitivity to changes in nominal yields, that is, to changes in inflation and real interest rate expectations. By contrast, the duration of an inflation-linked bond measures its sensitivity to changes in real yields, that is, to changes in real interest rate expectations alone. In other words, the two durations are not comparable: They are measuring different things. So, for example, it does not make sense to look for a “reference” nominal yield for the TIPS real yield: While the TIPS yield may appear to trade off the 10-year Treasury during some periods, or off the 5-year Treasury during other periods, there is no fundamental reason why any such relationship should persist.

This creates a problem at the portfolio level. If we try to compute a portfolio duration by adding up the durations of nominal and inflation-indexed bond holdings, what does the resulting figure mean? Two portfolios could have the same duration but, depending on the relative weighting of index-linked bonds, might have a very different response to a change in investors’ economic expectations. A simple duration target is no longer an

effective way of controlling portfolio interest rate risk.

Thus, when a portfolio contains both nominal and inflation-linked bonds, it is critical to monitor and report the relative weights and durations of the “nominal” and “real” components of the portfolio separately. One approach is to report two durations for the portfolio, which distinguish two sources of risk:

1. A “portfolio real yield duration” equal to the sum of the durations of both nominal and inflation-indexed bond holdings. This shows how the portfolio value will respond to a change in market real yields (which also affect nominal yields).
2. A “portfolio inflation duration” equal to the duration of the nominal bond holdings alone. This shows how the portfolio value will respond to a change in market inflation expectations (which affect nominal yields but not real yields).

Similarly, care must be taken when carrying out portfolio simulations. For example, when carrying out parallel interest rate simulations, it is standard practice to apply an identical yield shift to all securities in the portfolio. For a portfolio containing both nominal and inflation-indexed bonds, this actually corresponds to a “real yield simulation.” One should also carry out “expected inflation simulations,” where the yield shift is applied to nominal but not inflation-indexed bond yields.

There is one practical situation in which it makes sense to compare the durations of a nominal and inflation-indexed bond directly: when designing trading strategies based on expected inflation. Suppose the central banking authority is targeting a long-term core CPI inflation rate of no more than 2%; and suppose that the 10-year nominal yield is 3.5% while the 10-year real yield is 0.5%. This means that the market is predicting an average headline CPI inflation rate, over the next 10 years, of 3%. If one had faith in the central bank’s ability to meet its inflation target and one did not believe headline

CPI would consistently outpace core CPI over the next decade, nominal bonds would look undervalued relative to inflation-indexed bonds.

How should one exploit this perceived opportunity without changing exposure to other sources of risk? The correct way is to execute a duration-matched swap, selling 10-year inflation-indexed bonds and buying 10-year nominal bonds. If inflation expectations fall, the strategy would realize a profit. If real interest rate expectations change (i.e., if real yields change), there would be no effect—which is the intention. (This kind of strategy can be implemented more precisely using a full term structure of market inflation forecasts, and incorporating short horizon economist forecasts.)

The above duration calculation is based on the (known) real cash flows and discounts at the real yield. There are other potential ways to compute the “duration” of an inflation-linked bond, which involve forecasting the (unknown) nominal cash flows and discounting using nominal yields on a zero coupon curve basis. The three most obvious alternatives are:

1. Using a fixed inflation forecast, generate projected bond cash flows (one should use a forecast that ensures that the net present value of

the forecast cash flows, discounted using the current nominal zero coupon curve, is equal to the current bond price). Compute the duration of this fixed cash flow stream using ± 100 bp shifts in the nominal zero coupon curve.

2. The same, except that when shifting the zero coupon curve by ± 100 bp, one recalculates the bond cash flows based on a new inflation forecast, adjusted by $\pm 1\%$. That is, the cash flow stream is assumed to depend on the level of nominal yields.
3. The same, except that one adjusts the inflation forecast by an amount different from $\pm 1\%$. For example, Figure 4 shows that historically, a 10 bp rise in U.S. nominal yields corresponded, on average, to a 9 bp rise in market long-term inflation expectations (though with much variation around that average). Thus one might adjust the inflation forecast by (say) $\pm 0.9\%$. The precise number depends on the reference Treasury yield, and the historical period used to estimate the relationship.

In each case, some minor variations are possible; for example, either constant or time-varying inflation forecasts could be used. These

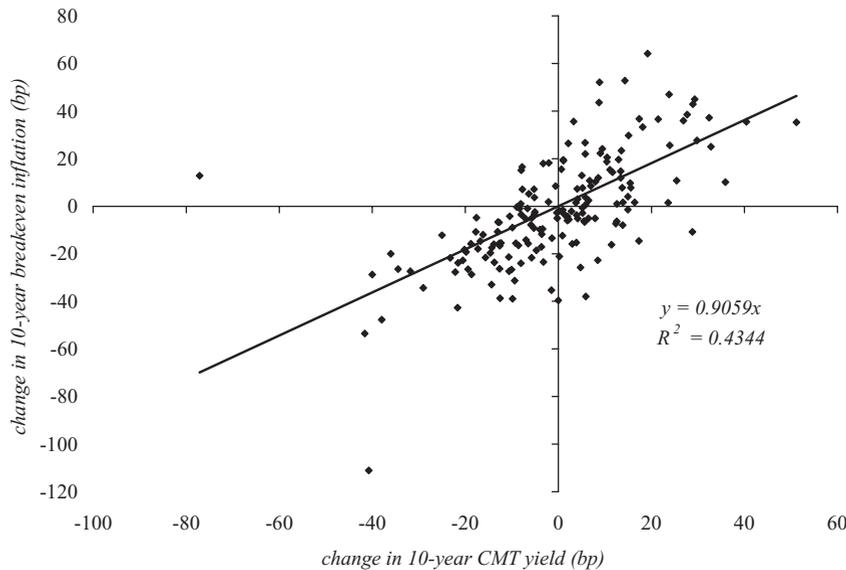

Figure 4 Shift in Nominal Yield versus Shift in Break-Even Inflation

calculations can be related to the above concepts of “real yield duration” and “inflation duration” in the following way:

1. Assuming a fixed cash flow stream (i.e., a fixed inflation scenario) amounts to assuming that the ± 100 bp shift in nominal yields is due to a change in real yields, not a change in inflation expectations. Thus, this calculation determines the sensitivity to a change in real yields, that is, it is essentially computing a real yield duration and produces an answer very close to the duration calculation described above.
2. Assuming an inflation scenario that varies by $\pm 1\%$ amounts to assuming that the ± 100 bp shift in nominal yields is due to a change in inflation expectations. Thus, this calculation measures an inflation duration, that is, a sensitivity to a shift in market inflation expectations, which is conceptually different from the real yield duration. The inflation duration of a TIPS will be approximately zero, but it may depend on the precise way the calculation is carried out.
3. Assuming an inflation scenario that varies by some amount based on the empirical relationship between nominal yields and market inflation expectations amounts to calculating a nominal yield duration, which attempts to measure the sensitivity of an inflation-linked bond to a shift in nominal yields.

Real yield duration is the most important of these risk measures—and, as we have seen, it can be calculated without using an inflation forecast. The inflation duration is not a useful risk measure for TIPS; however, in the U.K. and Australian markets, where inflation-indexed Treasuries have some residual inflation sensitivity due to the lag in inflation indexation, inflation duration is perhaps worth monitoring. The definition of nominal yield duration makes essential use of an estimate about an empirical relationship that is probably unstable, severely limiting the usefulness of this risk measure.

Note that if inflation-indexed Treasury bonds did have stable nominal durations—that is, if they did respond in an absolutely predictable way to a change in nominal yields—then they would not be a very useful risk management tool, since their mark-to-market behavior could be perfectly replicated by nominal bonds, which, moreover, are more liquid. In fact, experience shows that inflation-indexed bonds cannot be hedged perfectly with nominal bonds.

One can also attempt to compute a “tax-adjusted duration” for an inflation-linked bond, which takes its tax treatment into account; this may be of importance in the U.K., where inflation accruals are not taxed. In the U.S. market inflation-linked and nominal bonds are taxed on a broadly consistent basis; in particular, by analogy with Treasury STRIPS, the inflation adjustment to the bond principal is taxable as it occurs, and not simply at bond maturity. Thus, just as one continues to use pretax durations for Treasury STRIPS despite their tax treatment, it seems reasonable to use pretax durations for TIPS as well. The trading behavior of inflation-linked bonds in a range of markets suggests that pretax duration measures suffice for most day-to-day interest rate risk management. However, it is worth discussing tax briefly.

The Impact of Taxation: An Outline

Inflation-indexed bonds attempt to eliminate inflation risk, but it reappears on an after-tax basis. We begin with the fact that tax affects returns on both nominal bonds and inflation-indexed bonds in an unfortunate way: High inflation results in lower after-tax real returns. For inflation-indexed bonds, an investor would reason as follows:⁹

$$\begin{aligned}
 & \text{forecast after-tax real yield} \\
 &= \text{forecast after-tax nominal yield} \\
 &\quad - \text{forecast inflation} \\
 &= \text{tax rate} \times \text{forecast pretax nominal yield} \\
 &\quad - \text{forecast inflation} \\
 &= \text{tax rate} \times (\text{pretax real yield} \\
 &\quad + \text{forecast inflation}) - \text{forecast inflation}
 \end{aligned}$$

$$= \text{tax rate} \times \text{pretax real yield} - \\ (1 - \text{tax rate}) \cdot \text{forecast inflation}$$

For nominal bonds, the reasoning is similar:

$$\begin{aligned} &\text{forecast after-tax real yield} \\ &= \text{forecast after-tax nominal yield} \\ &\quad - \text{forecast inflation} \\ &= \text{tax rate} \times \text{forecast pretax nominal yield} \\ &\quad - \text{forecast inflation} \\ &= \text{tax rate} \times (\text{pretax real yield} \\ &\quad + \text{market inflation}) - \text{forecast inflation} \\ &= \text{tax rate} \times \text{pretax real yield} \\ &\quad - (\text{forecast inflation} \\ &\quad - \text{tax rate} \cdot \text{market inflation}) \end{aligned}$$

where “forecast inflation” refers to the investor’s inflation forecast and “market inflation” refers to the market’s inflation forecast as reflected in the spread between market nominal yields and market real yields.

Thus an investor who agrees with the market’s inflation forecast and who is thus indifferent between inflation-linked bonds and nominal bonds on a pretax basis will also be indifferent on an after-tax basis. The arguments show that projected after-tax real returns on both inflation-indexed and nominal bonds depend on forecast inflation.

An important consequence is that since U.S. inflation-indexed bonds and nominal bonds are affected equally, inflation-linked bonds do not protect investors against the negative after-tax impact of high inflation. Thus, TIPS real yields reflect only a premium for “pretax inflation risk.” By contrast, since U.K. index-linked gilts receive preferential tax treatment, their yields also reflect a premium for “after-tax inflation risk.” The price paid by U.K. investors, as observed by Roll (1996) and by Brown and Schaefer (1996), is lower liquidity: The market for index-linked gilts is confined to investors with high marginal tax rates and to investors who have other incentives, such as regulatory incentives, to own inflation-linked securities.¹⁰ Roll (1996) points out a further consequence: If the demand for inflation-indexed or nomi-

nal bonds is a function of expected after-tax returns, pretax real yields should rise as expected inflation rises, to maintain a constant after-tax real yield. It is not clear whether real yields on inflation-indexed bonds actually behave in this way, although the Australian experience in 1994 suggests that they do. In any case, this introduces a further source of uncertainty about the future behavior of real yields.

Inflation-Indexed Bonds and Portfolio Efficiency

Inflation-indexed bonds have a risk profile quite different from that of nominal bonds. In fact, it could be argued that for asset allocation purposes, they should not be grouped with nominal bonds but should be treated as an entirely separate asset class. We will use portfolio theory to explore the consequences of adopting this point of view. More specifically, we will try to determine what weight TIPS should have in efficient portfolios with varying degrees of risk, and what impact their inclusion has on expected returns.

For simplicity, we focus on maximizing nominal returns in the U.S. market, and we work in a total return framework. Other kinds of analysis are possible; for example, Eichholtz, Naber, and Petri (1993) discuss the problem of matching inflation-indexed liabilities in the U.K. and Israeli markets.

The results of any Markowitz-style analysis are always highly dependent on the expected returns, volatilities, and correlations used. The assumptions we use are set out in Table 1 and are broadly based on market data and presumed market expectations. They were derived as follows:

1. Expected nominal returns for cash and nominal bonds (aggregate bond index) are based on current market yields—this is more meaningful than using historical returns. For simplicity, we assume that nominal bonds and TIPS have the same expected return (in practice, one would derive expected returns more

Table 1 Assumptions Used in Efficient Portfolio Analysis

	Cash	Bonds	TIPS	Equities
Expected return	2.0%	2.8%	2.8%	5.8%
Return volatility	0.6%	3.6%	5.9%/3.6%	16.5%
Correlations				
Cash	1.00	0.06	-0.03	0.01
Bonds		1.00	0.73	-0.01
TIPS			1.00	0.03
Equities				1.00

carefully). The expected return for equities is obtained by adding a risk premium of 3% to that for bonds.

- Return volatilities for cash, nominal bonds, TIPS, and equities are historical, calculated using monthly Barclays index return data and S&P 500 return data over the period 1997–2011. In addition to the historical volatility for TIPS—which is quite high, largely due to the experience during the crisis period—we also carry out an alternative analysis that assumes that they have the same volatility as nominal bonds.
- We use historical correlations estimated using the same time period.

At first glance, the results seem highly dependent on the volatility assumption used for TIPS. Figure 5 shows the composition of theoretically efficient portfolios with varying degrees of risk, using the realistic volatility assumption; Figure 6 shows the same, using the low volatility assumption. Using the higher volatility, TIPS play almost no role in any efficient portfolio; for example, at moderate risk levels, nominal bonds are preferred because of their lower correlation with equities. However, using the lower volatility, TIPS have a much more important role to play. They partly displace cash at low risk levels, and more importantly they partly displace nominal bonds at moderate risk levels. Only the equity weightings remain more or less unchanged.

But how much value do TIPS actually add? Figure 7 shows the efficient frontier; that is, expected returns from efficient portfolios, calculated using both the realistic and low TIPS volatility assumptions. Above the 2% risk level, they are very close: Expected returns differ only marginally. That is, even assuming that TIPS will have a very low return volatility does not significantly increase their expected value

**Figure 5** Composition of Efficient Portfolios, 5.9% Volatility Assumption

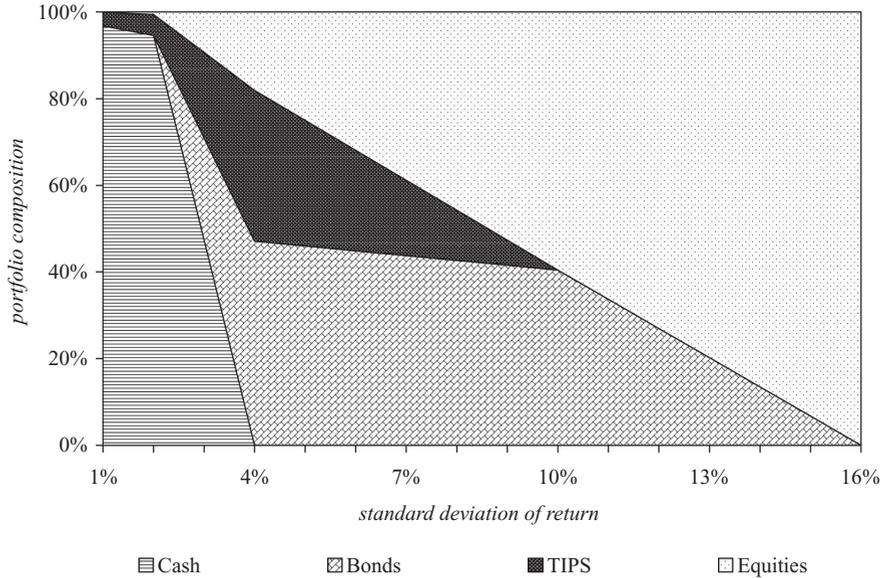

Figure 6 Composition of Efficient Portfolios, 3.6% Volatility Assumption

added to portfolio returns unless different expected return assumptions are used as well (or unless we move beyond the pure mean-variance framework).

Figure 8 is even more telling. It shows expected returns from efficient portfolios under the low TIPS volatility assumption for both

unconstrained portfolios and portfolios from which TIPS have been excluded. Even at moderate risk levels, where TIPS are most important, the difference in expected returns is extremely modest. Moreover, an investor who currently held a TIPS-free portfolio, and who wanted to capture these additional few basis points by

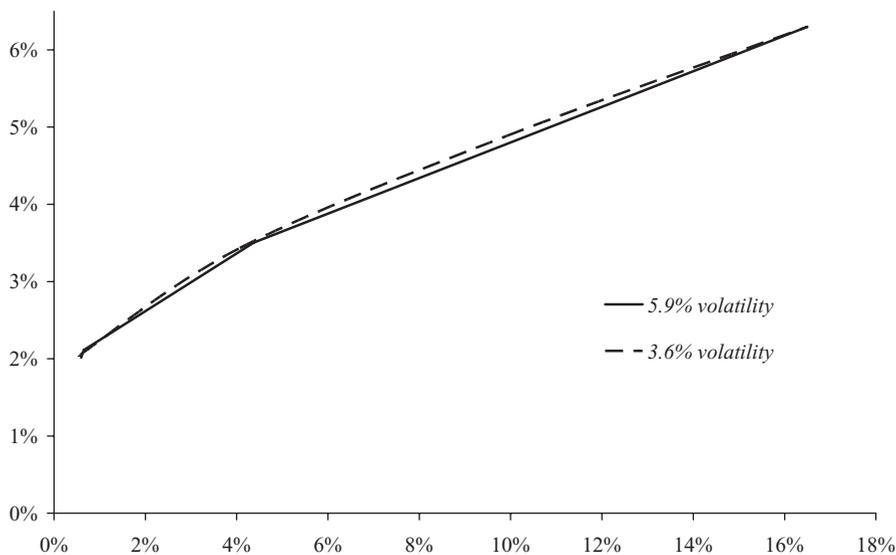

Figure 7 Efficient Frontier for the Two Different Volatility Assumptions

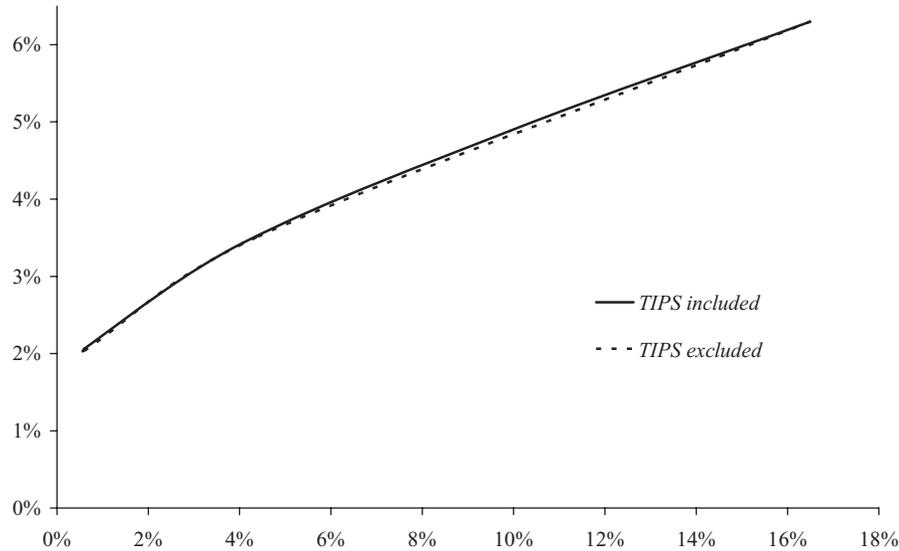

Figure 8 Efficient Portfolios Including and Excluding TIPS

purchasing TIPS, would have to trade over a quarter of the portfolio to achieve the optimal asset class weightings.

The overall conclusions are that (1) a realistic TIPS return volatility assumption, consistent with historical experience, implies that TIPS do not add much value to asset allocation; and (2) even under a very optimistic TIPS return volatility assumption, the value added by TIPS is modest. The main reasons are that TIPS do not have a higher expected return than nominal bonds, but have a slightly higher assumed correlation with equities.

These results should be compared with the findings of Eichholtz, Naber, and Petri (1993), who used data from 1983–1991 and discovered a significant difference between relatively low-inflation countries such as the U.K. in that period and countries such as Israel where inflation had been extremely high and volatile.

- Results for the U.K.: If the goal is to maximize total return, inflation-linked bonds do not appear in any efficient portfolio. If inflation-linked liabilities are included in the problem (but setting regulatory considerations aside), they appear in very low-risk efficient portfolios, but with negligible weight: less than 1%.

- Results for Israel: If the goal is to maximize total return, inflation-linked bonds play a minor role in low-risk portfolios but a major role in risky portfolios, sometimes having a weight of over 50%. If inflation-linked liabilities are included in the problem, inflation-linked bonds play a major role at all levels of risk, with weights between 44% and 88%.

TIPS provide insurance against inflation, and each investor's subjective assessment of future inflation risk and the need for inflation protection must strongly influence any conclusions about the role of TIPS. U.S. investors will have to decide which set of results provides more useful guidance.

ADVANCED ANALYTICAL APPROACHES TO INFLATION-INDEXED BONDS

As the U.S. TIPS market has matured, with a full term structure of maturities and a trading history spanning several business cycles and inflation environments, investors have developed many analytical approaches in the search for

investment opportunities. Rather than attempting a comprehensive survey, the remainder of this entry gives two brief examples, both of them focusing on economic factors rather than supply/demand relationships or “market technicals.” Standard econometric techniques turn out to be useful.

Link between TIPS Performance and Short-Term Inflation

The relative performance of TIPS versus nominal Treasuries is determined both by daily mark-to-market movements and by inflation accrual, which influences both inflation-adjusted principal and interest payments. Inflation accrual is clearly determined by realized headline CPI inflation (relative to nominal yields). Since headline CPI is quite volatile, this “carry” component of TIPS returns can often be a dominant factor in the performance of short and even intermediate maturity TIPS.

One useful way of looking at this is by isolating the impact of the more volatile components of CPI. Bryan and Meyer (2010) divide the CPI basket into “flexible price” and “sticky price” categories, leading to two separate measures

of inflation. Examples of flexible price items are gasoline, fruit and vegetables, and women’s apparel; examples of sticky price items are furniture, alcoholic beverages, and public transportation.

Figure 9 shows that during the period since the introduction of TIPS in 1997, there was a positive correlation between changes in 10-year TIPS break-even inflation and changes in three-month flexible price CPI inflation. It may seem surprising that 10-year inflation expectations are visibly influenced by realized three-month inflation; but this simply reflects the strong influence of carry on the trading behavior of TIPS, even 10-year maturity TIPS.

We can get a more refined view of the relationship if we run a vector autoregression analysis and examine the impulse-response functions. Some of the results from an analysis using 2003–2011 data on five-year TIPS (i.e., a shorter maturity, more strongly influenced by carry considerations) are shown in Figure 10. The impulse-response functions suggest that:

1. 5-year TIPS break-even inflation responds more strongly to flexible price CPI than

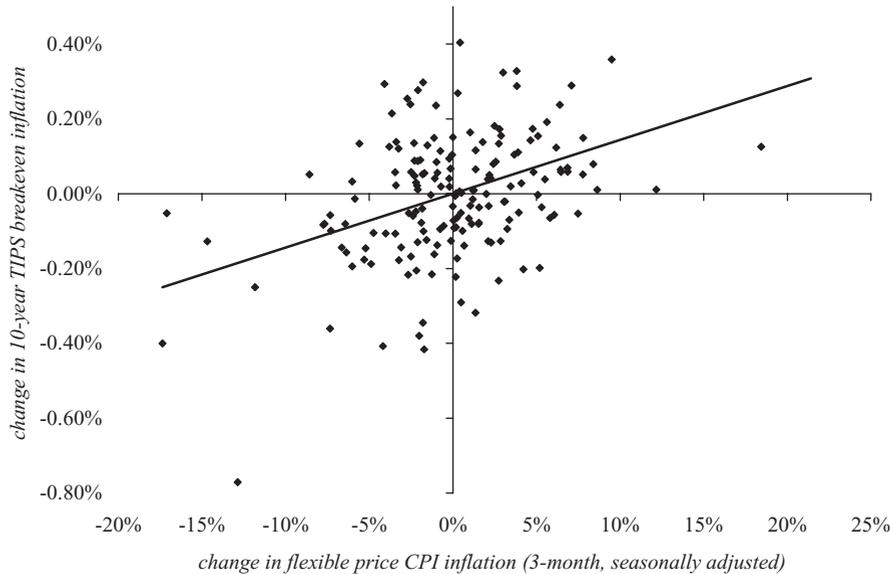

Figure 9 TIPS Performance and Flexible Price CPI

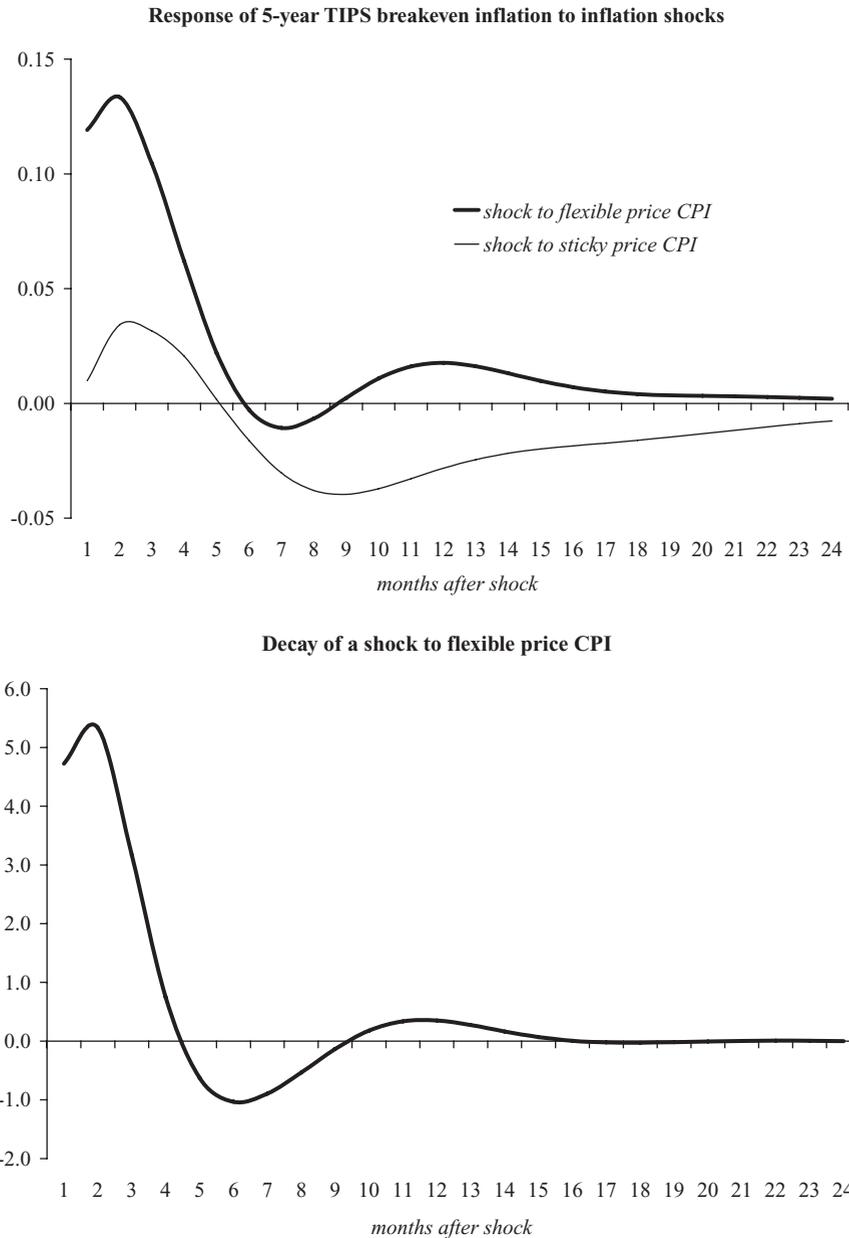

Figure 10 Five-Year TIPS Break-Even Inflation and Shocks to Flexible Price CPI Inflation

- to sticky price CPI, that is, the sources of shorter-term inflation volatility are more important; despite the fact that
2. Shocks to flexible price CPI inflation tend to be quite short-lived, dissipating after a couple of months and even tending to (partially) correct.

Since TIPS inflation accrual is based on non-seasonally-adjusted headline CPI inflation, a further aspect of TIPS carry is the strong seasonal pattern exhibited by CPI inflation. This needs to be analyzed separately. Seasonal factors have often been a source of market inefficiency in the past.

The TIPS Premium versus Survey-Based Real Yield Measures

As can be seen from Figure 1, TIPS real yields have usually (but not always) been higher than the real yields implied by subtracting consensus inflation forecasts from observed nominal Treasury yields. In other words, TIPS real yields usually incorporate an apparent “concession.” The historical behavior of this apparent real yield premium is shown in Figure 11, together with an estimate of its trend behavior (derived by applying a standard Hodrick-Prescott filter¹¹).

This premium has averaged around 40–50 bp, but has fluctuated quite a bit over time. It seems to mean revert to trend (heavy line in Figure 11) over about a 12-month period on average.

Why would this premium exist?

1. *Survey bias*: Economists’ forecasts of future inflation may be systematically biased (higher) relative to the market’s forecasts. This is more likely to have been true during the period of declining trend inflation from the mid-1980s to the mid-2000s; and indeed the real yield premium seems to have

decreased since then, though it has still been positive on average.

2. *Recalculation risk*: There may be a downward bias to the risk of future changes to the definition of CPI.¹²
3. *Liquidity*: TIPS are less liquid than nominals (i.e., they have wider and more uncertain bid/ask spreads, and greater market impact of large trades), so investors require a higher real yield to compensate for that.
4. *Tracking error*: TIPS aren’t in the standard bond indexes, so index-sensitive investors need to be compensated for the fact that owing TIPS leads to additional tracking error.
5. *Undesirable correlations*: TIPS tend to underperform in deflations/recessions, which is when investors most want bonds to do well; another kind of undesirable correlation is that TIPS liquidity tends to deteriorate in periods of general market stress.

The first two factors are difficult to quantify, but one could argue that their influence is probably fairly constant over time. It thus seems feasible to develop relative value measures conditioned on the remaining three factors, which are potentially more tractable.

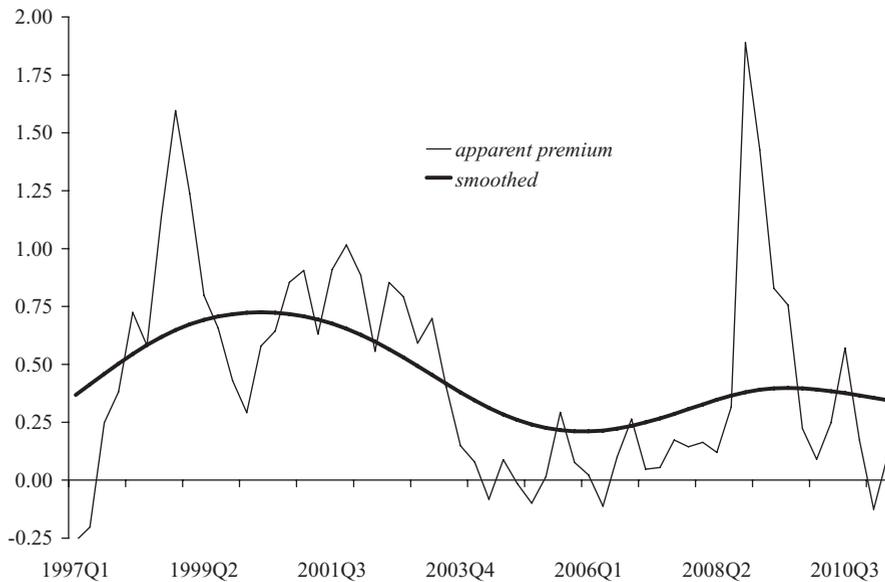

Figure 11 Apparent TIPS Real Yield Premium

The (il)liquidity premium turns out to be particularly important, since it exhibits the most time variation. It is difficult to estimate based on yield data alone;¹³ furthermore, as with all liquidity premiums, it is not fully determined by prevailing liquidity conditions (bid/ask spreads, quoted volumes, and market impact of trades) but is also influenced by the perceived risk that future liquidity conditions may differ from today's.

Modeling liquidity premiums is extremely difficult, but useful information can be extracted via model-free approaches. For example, Christensen and Gillan (2011) argue that the difference between TIPS break-even inflation and inflation swap rates provides a time-varying upper bound on the TIPS liquidity premium. This upper bound has typically fluctuated between 10 bp and 20 bp, but rose to over 100 bp in late 2008 during the financial crisis; it has been highly correlated with other measures of bond liquidity, such as the yield premium of off-the-run versus on-the-run nominal Treasuries.

KEY POINTS

- TIPS real yields are volatile. They are influenced by domestic growth, external balances, and the behavior of competing asset classes.
- TIPS real yields also reflect a modest and somewhat volatile inflation risk premium.
- There are different notions of *TIPS duration* corresponding to different aspects of TIPS interest rate risk.
- TIPS often do not play a significant role in efficient portfolios, and some investors may be better off regarding them as opportunistic rather than core investments.
- Market returns on TIPS are often driven by short-term inflation accrual, and this is best analyzed by breaking observed inflation down into suitable components.
- Survey-based measures of inflation and real yields often differ from those implied by the

TIPS market, and it is important for investors to understand the reasons for the divergence.

Credit Risk Modeling

An Introduction to Credit Risk Models

DONALD R. VAN DEVENTER, PhD

Chairman and Chief Executive Officer, Kamakura Corporation

Abstract: Credit risk technology has evolved with advances in computer science and information technology. Traditional credit ratings date back to 1860, an era when the cost of collecting and analyzing corporate credit information was high. The commercial advantages of a central provider of credit risk analysis were high. With the advent of better computer technology and databases of corporate financial information and stock prices, quantitative approaches to credit risk assessment have become more popular and increasingly accurate. Credit scoring is a quantitative approach to retail credit assessment, but, in the corporate world, more and more credit analysts prefer a default probability with an explicit maturity to a “credit rating” or “credit score.”

This entry introduces the topic of *credit risk modeling* by first summarizing the key objectives of credit risk modeling. We then discuss ratings and credit scores, contrasting them with modern *default probability* technology. Next, we discuss why valuation, pricing, and hedging of credit risky instruments are even more important than knowing the default probability of the issuer of the security. We review some empirical data on the consistency of movements between common stock prices and credit spreads with some surprising results. Finally, we compare the accuracy of ratings, the *Merton model* of risky debt, and reduced form credit models.

KEY OBJECTIVES IN CREDIT RISK MODELING

In short, the objective of the credit risk modeling process is to provide an investor with practical tools to “buy low/sell high.”¹ Robert Merton, in

a 2002 story retold by van Deventer, Imai, and Mesler (2004), explained how Wall Street has worked for years to get investors to focus on expected returns, ignoring risk, in order to get investors to move into higher risk investments. In a similar vein, investment banks have tried to get potential investors in collateralized debt obligations (CDOs) to focus on “expected loss” instead of market value and the volatility of that market value on a CDO. The result, according to the Global Stability Report of the International Monetary Fund, was an estimated \$945 billion in global credit losses during the credit crisis that began in earnest in 2007.²

This means that we need more than a default probability. The default probability provides some help in the initial yes/no decision on a new transaction, but it is not enough information to make a well-informed yes/no, buy/sell decision, as we discuss below. Once the transaction is done, we have a number of very critical objectives from the credit risk modeling

process. We need to know the value of the portfolio, the risk of the portfolio (as measured most importantly by the random variation in its value), and the proper hedge of the risk if we deem the risk to be beyond our risk appetite. Indeed, the best single sentence test of a credit model is “What is the hedge?” If one cannot answer this question, the credit modeling effort falls far short of normal risk management standards. It is inconceivable that an interest rate risk manager could not answer this question. Why should we expect any less from a credit risk manager, who probably has more risk in his area of responsibility than almost anyone else? Indeed, stress testing with respect to macroeconomic factors is now standard under proposals from the European Central Bank and under the U.S. programs titled “Supervisory Capital Assessment Program” and “Comprehensive Capital Analysis and Review.” The latter programs, applied to the 19 largest financial institutions in the United States, focused on macro factors like home prices, real gross domestic product growth, and unemployment.

RATINGS AND “CREDIT SCORES” VERSUS DEFAULT PROBABILITIES

Rating agencies have played a major role in fixed income markets around the world since the origins of Standard & Poor’s in 1860. Even the “rating agencies” of consumer debt, the credit bureaus, play prominently in the banking markets of most industrialized countries. Why do financial institutions use ratings and credit scores instead of default probabilities? As a former banker myself, I confess that the embarrassing answer is “There is no good reason” to use a rating or a credit score as long as the *default probability modeling* effort is a sophisticated one and the inputs to that model are complete.

Ratings have a lot in common with interest accrual based on 360 days in a year. Both ratings and this interest accrual convention date

from an era that predates calculators and modern default probability technology. Why use a debt rating updated every 1–2 years when one can literally have the full term structure of default probabilities on every public company updated daily or in real time? In the past, there were good reasons for the reliance on ratings:

- Default probability formulas were not disclosed, so proper corporate governance would not allow reliance on those default probabilities.
- Default probability model accuracy was either not disclosed or disclosed in such a way that weak performance was disguised by selecting small sectors of the covered universe for testing.
- Default probability models relied on old technology, like the Merton model of risky debt and its variants, that has long been recognized as out of date.³
- Default probability models implausibly relied on a single input (the unobservable value of company assets), ignoring other obvious determinants of credit risk like cash balances, cash flow coverage, the charge card balance of the CEO of a small business, or the number of days past due on a retail credit.

With modern credit technology, none of these reasons are currently valid because there is a rich, modern credit technology available with full disclosure and an unconstrained ability to take useful explanatory variables. In this vein, ratings suffer from a number of comparisons to the modern credit model:

- Ratings are discrete with a limited number of grades. There are 21 Standard & Poor’s ratings grades, for example, running from AAA to D. Default probabilities are continuous and run (or should run) from 0 to 100%.
- Ratings are updated very infrequently and there are obvious barriers that provoke even later than usual response from the rating agencies, like the 2004 downgrade from AAA to AA- for Merck, a full three weeks after the

withdrawal of its major drug Vioxx crushed the company’s stock price. Another example is General Electric, first rated AAA in 1956, which was not downgraded until March 2009, a full four months after General Electric was forced to borrow under the Federal Reserve’s Commercial Paper Funding Facility.⁴ Default probabilities can adjust in real time if done right.

- Ratings have an ambiguous maturity, which we discuss in the next section. The full term structure of default probabilities is available and the obvious impact of the business cycle is observable: The full default probability term structure rises and falls through the business cycle, with short-term default probabilities rising and falling more dramatically than long-term default probabilities. Figure 1 illustrates this cyclical rise and fall during the credit crisis of 2007–2011 for Bank of America Corporation and Citigroup, two of the largest U.S. bank holding companies, using the reduced form model default probabilities discussed below and provided by Kamakura Corporation.

The cyclical rise and fall of default probabilities for both banks are very clear and show the impact of the credit crisis, which was at its height in 2007–2009. We take a longer-term view from 1990 to 2006 below.

Figure 2 shows clearly the joint rise in default probabilities in 1990–1991, a mini recession in 1994–1995, and the impact of the Russian debt crisis and high-tech crash in 1998–2002. By way of contrast, Standard & Poor’s only changed its ratings on Bank of America twice in the 1995–2006 period, once in 1996 and once in 2005.

What about consumer and small business “credit scores”? Like ratings and the interest accrual method mentioned above, these date from an era when there was limited understanding of credit risk in the financial community. Vendors of credit scores had two objectives in marketing a credit risk product: to make it simple enough for any banker to understand and to avoid angering consumers who might later learn how they are ranked under the credit measure. The latter concern is still, ironically, the best reason for the use of credit scores instead of default probabilities today on the retail side. From a

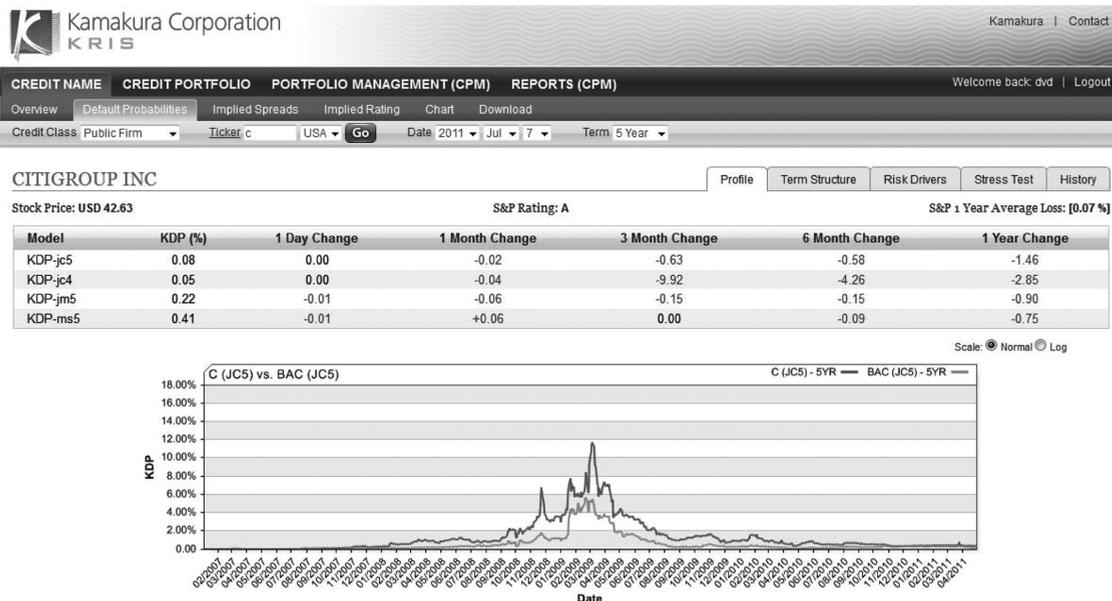

Figure 1 Five-Year Default Probabilities for Bank of America and Citigroup: January 1, 2007 to May 1, 2011

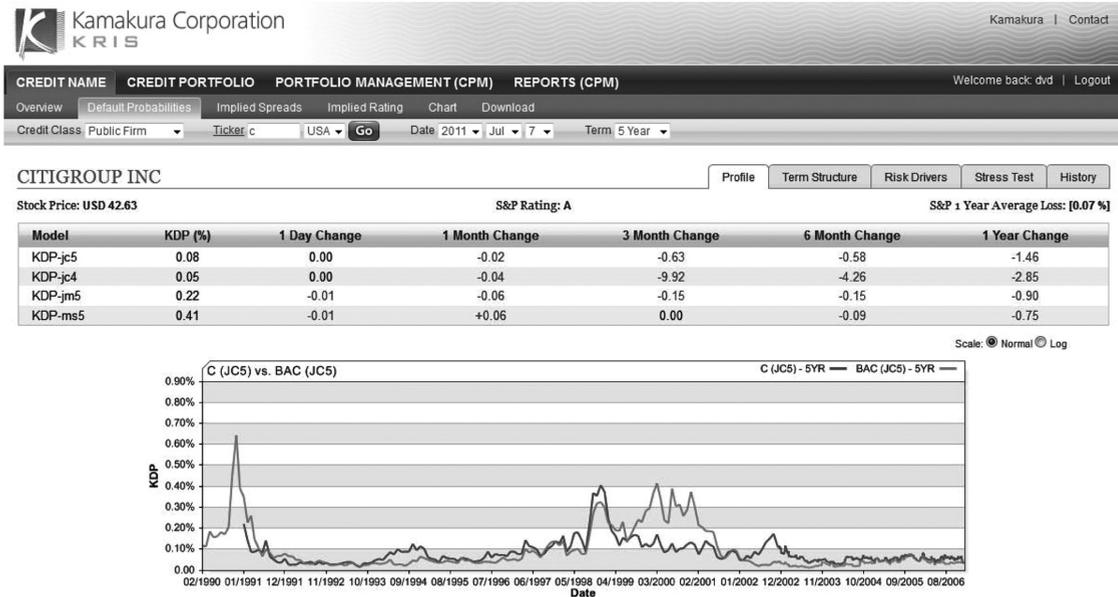

Figure 2 Five-Year Default Probabilities for Bank of America and Citigroup: January 1, 1990 to December 31, 2006

banker's perspective, though, the score hides information that is known to the credit score vendor. The credit scoring vendor is actually using the statistical techniques we describe below to derive a default probability for the consumer. They then hide it by scaling the default probability to run from some arbitrary range like 600 to 1,000 with 1,000 being best.⁵ One scaling that does this, for example, is the formula:

$$\text{Credit score} = 1,000 - 4 (\text{Consumer 1-year default probability})$$

This scaling formula hides the default probability that Basel II requires and modern bankers are forced to "undo" by analyzing the mapping of credit scores to defaults. This just wastes everyone's time for no good reason other than the desire to avoid angering retail borrowers with a cold-hearted default probability assessment.

The only time a rating or credit score can outperform a modern credit model is if there are variables missing in the credit model. Heading into the credit crisis as of December 31, 2006, for example, Citigroup had a roughly \$50 billion direct and indirect exposure to super senior

tranches of collateralized debt obligations, but these exposures were not reported in a quantitative form and therefore could not be used in a quantitative credit model. A judgmental rating in this case would be able to adjust for this risk if proper disclosure were made to the rating agencies. This, however, is a rare case and in general a first-class modeling effort will be consistently superior.⁶

WHAT "THROUGH THE CYCLE" REALLY MEANS

Financial market participants often comment that default probabilities span a specific period of time (30 days, 1 year, 5 years) while ratings are "through the cycle" ratings. What does "through the cycle" really mean?

Figure 3 provides the answer. It shows the term structure of default probabilities out for 10 years for Morgan Stanley on October 15, 2008, one month after the collapse of Lehman Brothers, and July 7, 2011. The July 7, 2011 term structure was quite low because business

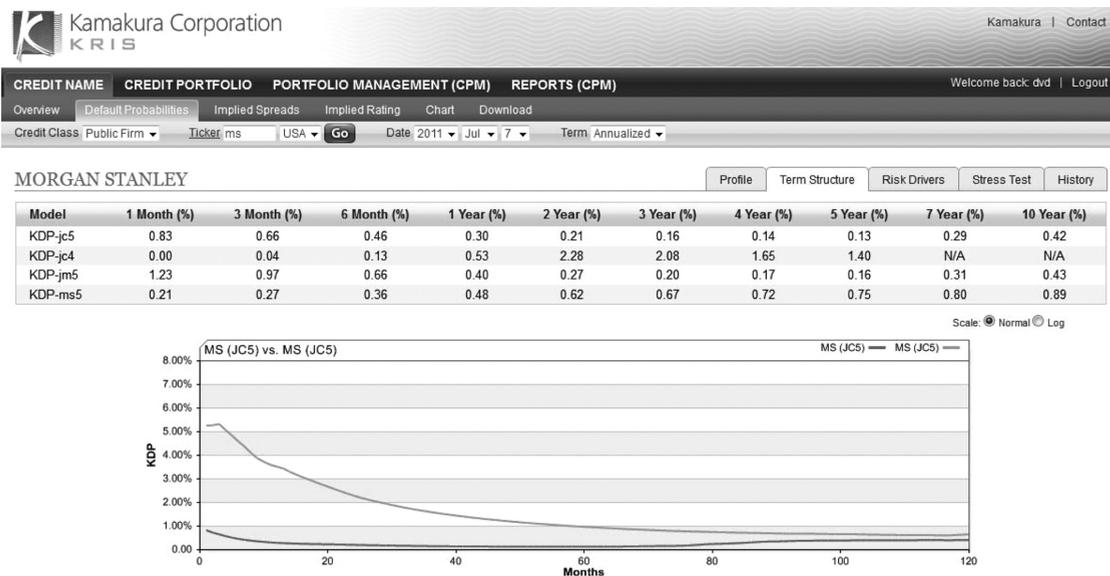

Figure 3 Term Structure of Default Probabilities for Morgan Stanley on October 15, 2008 and July 7, 2011

conditions at the time were excellent.⁷ Looking at the right-hand side of the curve, we can see that both default probability curves are converging and, if the graph is continued to a long enough maturity, both will hit about 42–50 basis points for a very long-term default probability.

This is consistent with the “long-run” default experience for both Morgan Stanley’s 2011 rating of A.⁸ Over the 15 years after being rated A, 2.77% of those formerly rated A defaulted. This is the same as a constant default rate over those 15 years of 18.7 basis points, a rate double the 8 basis point default rate in just the first one year after being rated A. Morgan Stanley is a higher than average risk for an A-rated company as it was forced to borrow as much as \$61.3 billion from the Federal Reserve on September 29, 2008.⁹ “Through the cycle” has a very simple meaning—it is a very long-term default probability that is totally consistent with the *term structure of default probabilities* of a well-specified model. What is the term? The major rating agencies are currently reporting about 30 years of historical experience, so the answer is 30 years.

VALUATION, PRICING, AND HEDGING

Earlier in this entry, we said the best one-sentence test of a credit model is “what is the hedge?” That statement is no exaggeration, because in order to be able to specify the hedge, we need to be able to value the risky credit (or portfolio of risky credits). If we can value the credits, we can price them as well. If we can value them, we can stress test that valuation as macroeconomic factors driving default probabilities shift. The pervasive impact of macroeconomic factors on default probabilities Figure 1 shows for Bank of America and Citigroup makes obvious what is documented by van Deventer and Imai (2003). The business cycle drives default risk (and valuations) up and down. With this valuation capability, we can meet one of the key objectives specified in this entry: We know the true value of everything we own and everything Wall Street wants us to buy or sell. We can see that the structured product offered at 103 is in reality only worth 98. This capability is essential to meet modern risk management

standards. Just as important, it is critical insurance against becoming yet another victim of Wall Street.

EMPIRICAL DATA ON CREDIT SPREADS AND COMMON STOCK PRICES

Before exploring the nature and performance of modern credit models, it is useful to look at the relationship between stock prices and credit spreads. Van Deventer and Imai (2003) print in its entirety a useful data series of new issue credit spreads compiled over a nine-year period beginning in the mid-1980s by First Interstate Bancorp. First Interstate at the time was the seventh largest bank holding company in the United States, one of the largest debt issuers in the United States, and a company whose rating ranged from AA to BB during the course of the data series. The credit spreads were the average credit spread quoted for a new issue of noncall debt of \$100 million by six investment banking firms, with the high and low quotations thrown out. Data were collected weekly for 427 weeks. No yield curve smoothing or secondary market bond prices were necessary to get the spreads, as the spreads themselves were the pricing quotation. These data, in the author's judgment, are much more reliable than the average credit default swap spread available since 2003 because of the extremely low volumes of credit default swap transactions reported by the Depository Trust and Clearing Corporation on www.dtcc.com.

Jarrow and van Deventer (1998, 1999) first used these data to test the implications of credit models. They reported the following findings on the relationship between credit spreads and equity prices:

- Stock prices and credit spreads moved in opposite directions during the week 172–184 times (depending on the maturity of the credit spread) of the 427 observations.

- Stock prices and credit spreads were both unchanged in only 1–3 observations.
- In total, only 40.7% to 43.6% of the observations were consistent with the Merton model (and literally any of its single factor variants) of risky debt.

This means that multiple variables are impacting credit spreads and stock prices, not the single variable (the value of company assets) that is the explanatory variable in any of the commercially available implementations of default probabilities that are Merton related. We address this issue in detail in our discussion of the Merton model¹⁰ and its variants in the following section. The summary data on the First Interstate stock price and credit spreads are reproduced in Table 1.

STRUCTURAL MODELS OF RISKY DEBT

Modern derivatives technology was the first place analysts turned in the mid-1970s as they sought to augment Altman's early work on corporate default prediction with an analytical model of default.¹¹ The original work in this regard was done by Black and Scholes (1973) and Merton (1974). This early work and almost all of the more recent extensions of it share a common framework:

- The assets of the firm are assumed to be perfectly liquid and are traded in efficient markets with no transactions costs.
- The amount of debt is set at time zero and does not vary.
- The value of the assets of the firm equal the sum of the equity value and the sum of the debt value, the original Modigliani and Miller assumptions.

All of the analysts using this framework conclude that the equity of the firm is some kind of option on the assets of the firm. An immediate implication of this is that one variable (except

Table 1 Analysis of Changes in First Interstate Bancorp Credit Spreads Stock Prices

Source: van Deventer and Imai (2003).

in the cases of random interest rates assumed below), the random value of company assets, completely determines stock prices, debt prices, and credit spreads. Except for the random interest rate versions of the model, this means that when the value of company assets rises, then stock prices should rise and credit spreads should fall. Table 1 rejects the hypothesis that this result is true by 23.5 to 24.9 standard deviations using the First Interstate data described earlier. In fact, as the First Interstate data show, stock prices and credit spreads move in the direction implied by various versions of the Merton model only 40.7% to 43.6% of the time. Van Deventer and Imai (2003) report on a similar analysis for a large number of companies with more than 20,000 observations and find similar results.

Given this inconsistency of actual market movements with the strongly restrictive assumption that only one variable drives debt and equity prices, why did analysts choose the structural models of risky debt in the first place? Originally, the models were implemented on the hope (and sometimes belief) that performance must be good. Later, once the performance of the model was found to be poor, this knowledge was known only to very large financial institutions who had an extensive credit model testing regime. One very large institution, for example, told the author in 2003 that it had known for years that the most popu-

lar commercial implementation of the Merton model of risky debt was less accurate than the market leverage ratio in the ordinal ranking of companies by riskiness. The firm was actively using this knowledge to arbitrage market participants who believed, but had not confirmed, that the Merton model of risky debt was accurate. We report on the large body of test results that began to enter the public domain in 1998 in a later section.

As analysts began to realize there were problems with the structural models of risky debt, active attempts were made to improve the model. We present in the following paragraphs a brief listing of the types of assumptions that can be used in the structural models of risky debt.¹²

Pure Black-Scholes/Merton Approach

The original Merton model assumes interest rates are constant and that equity is a European option on the assets of the firm. This means that bankruptcy can occur only at the maturity debt of the single debt instrument issued by the firm. Lando (2004, p. 14) notes a very important liability of the basic Merton model as the maturity of debt gets progressively shorter: "When the value of assets is larger than the face value of debt, the yield spreads go to zero as time

to maturity goes to 0 in the Merton model.” This is a critical handicap in trying to use this one-period model as a complete valuation framework. If credit spreads are unrealistic, we cannot achieve accuracy in our one-sentence credit model test: What’s the hedge?

We note here that allowing for various classes of debt is a very modest extension of the model. Allowing for subordinated debt does not change the probability of default. The implicit loss given default will simply be higher for the subordinated debt issue than it will for the senior debt issue.

Merton Model with Stochastic Interest Rates

The Merton model with stochastic interest rates was published by Shimko, Tejima, and van Deventer (1993). This modest extension of the original Merton framework simply combined Merton’s own model for options when interest rates are random with the structural credit risk framework. The model has the virtue of allowing two random factors (the risk-free short-term rate of interest and the value of company assets, which can have any arbitrary degree of correlation). It provides at least a partial explanation of the First Interstate results discussed above, but it shares most of the other liabilities of the basic Merton approach.

The Merton Model with Jumps in Asset Values

One of the most straightforward ways in which to make credit spreads more realistic is to assume that there are random jumps in the value of company assets, overlaid on top of the basic Merton assumption of geometric Brownian motion (i.e., normally distributed asset returns and lognormally distributed asset values). This model produces more realistic credit spread values, but Lando (2004, p. 27) concludes, “while the jump-diffusion model is

excellent for illustration and simulating the effects of jumps, the problems in estimating the model make it less attractive in practical risk management.”

Introducing Early Default in the Merton Structural Approach

In 1976, Black and Cox allowed default to occur prior to the maturity of debt if the value of company assets hits a deterministic barrier that can be a function of time. The value of equity is the equivalent of a “down and out” call option. When there are dividend payments, modeling gets much more complicated. Lando (2004, p. 33) summarizes key attributes of this modeling assumption: “While the existence of a default barrier increases the probability of default in a Black-Cox setting compared with that in a Merton setting, note that the bond holders actually take over the remaining assets when the boundary is hit and this in fact leads to higher bond prices and lower spreads.”

Other Variations on the Merton Model

Other extensions of the model summarized by Lando include

- A Merton model with continuous coupons and perpetual debt.
- Stochastic interest rates and jumps with barriers in the Merton model.
- Models of capital structure with stationary leverage ratios.

Ironically, all current commercial implementations of the Merton model for default probability estimation are minor variations on the original Merton model or extremely modest extensions of Black and Cox (1976). In short, at best 34-year-old technology is being used. Moreover, all current commercial implementations assume interest rates are constant, making failure of the “What’s the hedge test” a

certainty for fixed income portfolio managers, the primary users of default technology. All of the problems raised in the previous section on the First Interstate dataset remain for all current commercial implementations. That has much to do with the empirical results summarized below.

REDUCED-FORM MODELS OF RISKY DEBT

The many problems with the major variations on the Merton approach led Jarrow and Turnbull (1995) to elaborate on a reduced form of the original Merton model. In his options model for companies where the stock price is lognormally distributed, Merton allowed for a constant instantaneous default intensity. If the default event occurred, the stock price was assumed to go to zero. Merton derived the value of options on a defaultable common stock in a constant interest rates framework. Van Deventer (2006) shows how to use this Merton “reduced form” model to imply default probabilities from observable put and call options.

Jarrow and Turnbull adopted this default intensity approach as an alternative to the Merton structural approach. They did so under the increasingly popular belief that companies’ choices of capital structure vary dynamically with the credit quality of the firm, and that the assets they hold are often highly illiquid, contrary to the assumptions in the structural approach. Duffie and Singleton (1999), Jarrow (2001), and many others have dramatically increased the richness of the original Jarrow-Turnbull model to include the following features:

- Interest rates are random.
- An instantaneous default intensity is also random and driven by interest rates and one or more random macroeconomic factors.
- Bonds are traded in a less liquid market, and credit spreads have a “liquidity premium”

above and beyond the loss component of the credit spread.

- Loss given default can be random and driven by macroeconomic factors as well.

Default intensities and the full term structure of default probabilities can be derived in two ways:

- By implicit estimation, from observable bond prices, credit default swap prices, or options prices or any combination of them
- By explicit estimation, using a historical default database

The first commercial implementation on a sustained basis of the latter approach was the 2002 launch of the Kamakura Risk Information Services multiple models default probability service, which includes both Merton and reduced form models benchmarked in historical default data bases. The first commercial implementation of this approach for sovereign default risk assessment was also by Kamakura Risk Information Services in 2008.

In deriving default probabilities from historical data, financial economists have converged on a hazard rate modeling estimation procedure using logistic regression, where estimated default probabilities $P[t]$ are fitted to a historical database with both defaulting and nondefaulting observations and a list of explanatory variables X_i . Chava and Jarrow (2004) prove that the logistic regression is the maximum likelihood estimator when trying to predict a dependent variable that is either one (i.e., in the default case) or zero (in the “no default” case):

$$P[t] = 1/[1 + \exp(-\alpha - \sum_{i=1}^n \beta_i X_i)]$$

This simple equation makes obvious the most important virtue of the reduced form approach. The reduced form approach can employ any variable, without restriction, that improves the quality of default prediction, because any variable can contribute in the equation above including Merton default probabilities if they

have explanatory power. This means that the reduced form approach can never be worse than the Merton model because the Merton model can always be an input. The reverse is not true—the charge card balance of the chief executive officer is a well-known predictor of small business default, but the Merton default formulas do not have the flexibility to use this insight. Note also that the linear function in the denominator can be thought of as Altman’s 1968 z-score concept. In that sense, the reduced form/logistic regression approach has both Altman’s work and Merton’s work as ancestors.

In short, reduced form models can be the result of unconstrained variable selection among the full set of variables that add true economic explanatory power to default prediction. The Merton model, in any variation, is a constrained approach to default estimation because the mathematical formula for the model does not allow many potential explanatory variables to be used.

Most importantly, the logistic regression approach provides a solid opportunity to test whether in fact the Merton model does have the problems one would predict from the First Interstate data discussed above. We turn to that task now.

EMPIRICAL EVIDENCE ON MODEL PERFORMANCE

Shumway and Bharath (2008) conduct an extensive test of the Merton approach. They test two hypotheses. Hypothesis 1 is that the Merton model is a “sufficient statistic” for the probability of default, that is, a variable so powerful that in a logistic regression like the formula in the previous section no other explanatory variables add explanatory power. Hypothesis 2 is the hypothesis that the Merton model adds explanatory power even if common reduced form model explanatory variables are present. They specifically test modifications of the Merton structure partially disclosed by commercial

vendors of the Merton model. The Shumway and Bharath (2008) conclusions, based on all publicly traded firms in the United States (except financial firms) using quarterly data from 1980 to 2003 are as follows:¹³

- “We conclude that the . . . Merton model does not produce a sufficient statistic for the probability of default.”
- “Models 6 and 7 include a number of other covariates: the firm’s returns over the past year, the log of the firm’s debt, the inverse of the firm’s equity volatility, and the firm’s ratio of net income to total assets. Each of these predictors is statistically significant, making our rejection of hypothesis one quite robust. Interestingly, with all of these predictors included in the hazard model, the . . . Merton probability is no longer statistically significant, implying that we can reject hypothesis two.”
- “Looking at CDS implied default probability regressions and bond yield spread regressions, the . . . Merton probability does not appear to be a significant predictor of either quantity when our naïve probability, agency ratings and other explanatory variables are accounted for.”

These conclusions have been confirmed by Kamakura Corporation in five studies done in 2002, 2003, 2004, 2006, and 2011. The current Kamakura default database includes more than 1.76 million monthly observations on all public companies in North America from 1990 to December 2008, including 2,046 defaulting observations. Both hypotheses 1 and 2 were tested in the context of a “hybrid” model, which adds the Kamakura Merton implementation as an additional explanatory variable alongside the Kamakura reduced form model inputs. In every case, Kamakura agrees with Shumway and Bharath that hypothesis 1 can be strongly rejected. Kamakura has found 49 other variables that are statistically significant predictors of default even when Merton default probabilities are added as an explanatory variable.

Somewhat different from Shumway and Bharath, Kamakura finds that the Merton default probability has weak statistical significance when added as an explanatory variable to these other 49 variables, but the coefficient on the Merton default probability has the wrong sign; when Merton default probabilities rise, the predicted hybrid default probabilities fall. This is because Merton default probabilities are highly correlated with other variables like the market leverage ratio (which was mentioned above as out-predicting the commercial Merton implementation) and the ratio of total liabilities to total assets. It is an interesting econometric question whether the Merton input variable should be retained in such an event.

These findings were indirectly confirmed in Bohn, Arora, and Korablev (2005), in which Moody's for the first time releases quantitative test results on their Merton implementation. In that paper, the authors report on the relative accuracy of their proprietary Merton implementation compared to the more standard Merton theoretical implementation; they state that on a relatively easy data set (1996–2004 with small firms and financial institutions excluded) the proprietary Merton implementation has a receiver operating characteristics (ROC) accuracy ratio 7.5% higher than the standard Merton implementation.¹⁴ This puts the accuracy of the Moody's model more than 5% below that reported on a harder data set (all public firms of all sizes, including banks, 1990–2004) in the Kamakura Risk Information Services Technical Guide, Version 4.1 (2005) and again in the Kamakura Risk Information Services Guide, Version 5.0 (2010) on data spanning 1990–2008. The accuracy is also well below reduced form model accuracy published in Bharath and Shumway (2008), Campbell, Hilscher, and Szilagyi (2008), Hilscher and Wilson (2011), van Deventer and Imai (2003), and van Deventer, Imai, and Mesler (2004). The standard Merton accuracy ratio reported by Bohn, Arora, and Korablev (2005) is identical to that reported by Kamakura on a harder data set. It is

not surprising that there were no comparisons to reduced-form models using logistic regression in Bohn, Arora, and Korablev.

KEY POINTS

- Ratings date from the founding of a predecessor of Standard & Poor's in 1860. The very existence of ratings as a credit assessment tool dates from an era when computers did not exist and the electronic transmission of financial information was impossible.
- Because of this history, ratings are extremely simple ordinal rankings of firms or other counterparties by a small number of ratings grades, 21 grades in the case of the U.S. rating agencies.
- Ratings have no explicit maturity and no explicit default probability associated with them.
- For consumer credit risk assessment, "credit scores" are similar to ratings in that they are an ordinal risk measure, they have no maturity, and they have no explicit default probability associated with the score. While some credit bureaus state that credit scores rank the risk of a 90-day past due experience over 24 months, they are used on the full spectrum of credits from charge cards to 30-year mortgages.
- Unlike ratings, which have both qualitative and quantitative inputs to the process, the creation of credit scores is fully automated and based on a sophisticated statistical process.
- In the modern era, there is no need for either ratings or credit scores if the credit analyst has access to best in class default probabilities for a full term structure of time horizons for each counterparty.
- The ratings debate about "point in time" and "through the cycle" is a distinction without a difference. All ratings reflect information as of the ratings announcement date, as do default probabilities, so they are in that sense a "point in time." The longest term default probability

is the best measure of long-term risk and the shortest term default probability is the best measure of short-term risk. The longest default probability is “through the cycle” if the maturity is long enough. The maturity of the rating has never been clearly articulated by the rating agencies themselves.

- The first attempts at measuring default probabilities were based on the early work by Robert Merton nearly 40 years ago. Merton’s theory is simple and has intuitive appeal.
- The Merton model has not been accurate in practical use because it is based on assumptions that are simply not true: that common stock prices and bond prices are driven by only one factor, the value of company assets, and that company assets are perfectly liquid.
- A modern reduced form approach will always be more accurate than the Merton approach because the reduced form approach can employ any input that makes economic sense and improves accuracy.
- Logistic regression is the maximum likelihood estimator for prediction of a variable that has a zero (no default) or one (default) value.
- Reduced form default models were introduced by Jarrow based on an early continuous time default model by Merton. Empirical evidence suggests reduced form models are more accurate than ratings and the Merton approach in predicting default.
- Reduced form default models were first launched commercially in 2002 for public firms and in 2008 for sovereigns. They are also in wide use for predicting default of retail and small business clients.

Default Correlation in Intensity Models for Credit Risk Modeling

ABEL ELIZALDE, PhD

Credit Derivatives Strategy, J.P. Morgan

Abstract: The two primary types of credit risk models that seek to statistically describe default processes are the reduced-form model and the structural model. The most extended types of reduced-form models are the intensity models. There are three main approaches to incorporate credit risk correlation among firms within the framework of reduced models. The first approach, the conditionally independent defaults models, introduces credit risk dependence among firms through the dependence of the firms' default intensity processes on a common set of state variables. Contagion models extend the conditionally independent defaults approach to account for default clustering (periods in which the firms' credit risk is increased and in which the majority of the defaults take place). Finally, default dependencies can also be accounted for using copula functions. The copula approach takes as given the marginal default probabilities of the different firms and plugs them into a copula function, which provides the model with the default dependence structure.

There are two primary types of models in the literature that attempt to describe default processes for debt obligations and other defaultable financial instruments, usually referred to as structural and *reduced-form* (or *intensity*) models.

Structural models use the evolution of firms' structural variables, such as asset and debt values, to determine the time of default. Merton's model (1974) was the first modern model of default and is considered the first structural model. In Merton's model, a firm defaults if, at the time of servicing the debt, its assets are below its outstanding debt. A second approach within the structural framework was introduced by Black and Cox (1976). In this approach defaults occur as soon as a firm's asset value falls below a certain threshold. In con-

trast to the Merton approach, default can occur at any time.

Reduced-form models do not consider the relation between default and firm value in an explicit manner. Intensity models represent the most extended type of reduced-form models.¹ In contrast to structural models, the time of default in intensity models is not determined via the value of the firm, but it is the first jump of an exogenously given jump process. The parameters governing the default hazard rate are inferred from market data.

Structural default models provide a link between the credit quality of a firm and the firm's economic and financial conditions. Thus, defaults are endogenously generated within the model instead of exogenously given as in the

reduced approach. Another difference between the two approaches refers to the treatment of recovery rates: Whereas reduced models exogenously specify recovery rates, in structural models the value of the firm's assets and liabilities at default will determine recovery rates.

This entry focuses on the intensity approach, analyzing various models and reviewing the three main approaches to incorporate credit risk correlation among firms within the framework of reduced-form models.

PRELIMINARIES

In this section, we fix the information and probabilistic framework we need to develop the theory of reduced-form models. After presenting the basic features of reduced models and the motivation of the default intensity through Poisson processes, we apply these concepts to the specification of single firm default probabilities and to the valuation formulas for defaultable and default-free bonds. Finally, we analyze the different treatments the recovery rate has received in the literature.

Information Framework

For the purposes of this investigation, we shall always assume that economic uncertainty is modeled with the specification of a filtered probability space $\Pi = (\Omega, \mathcal{F}, (\mathcal{F}_t), \mathbf{P})$, where Ω is the set of possible states of the economic world, and \mathbf{P} is a probability measure. The filtration (\mathcal{F}_t) represents the flow of information over time. $\mathcal{F} = \sigma(\bigcup_{t \geq 0} \mathcal{F}_t)$ is a σ -algebra, a family of events at which we can assign probabilities in a consistent way.² Before continuing with the exposition, let us make some remarks about the choice of the probability space.

First, we assume, as a starting point, that we can fix a unique physical or real probability measure $\bar{\mathbf{P}}$, and we consider the filtered probability space $\tilde{\Pi} = (\Omega, \mathcal{F}, (\mathcal{F}_t), \bar{\mathbf{P}})$. The choice of

the probability space will vary in some respects, according to the particular problems under consideration. In the rest of the entry, as we indicated above, we shall regularly make use of a probability measure \mathbf{P} , that will be assumed to be equivalent to $\bar{\mathbf{P}}$. The choice of \mathbf{P} then varies according to the context.

The model for the default-free term structure of interest rates is given by a non-negative, bounded and (\mathcal{F}_t) -adapted default-free short-rate process r_t . The money market account value process is given by:

$$\beta_t = \exp\left(\int_0^t r_s ds\right) \quad (1)$$

For our purposes we shall use the class of equivalent probability measures \mathbf{P} , where non-dividend-paying (NDP) asset processes discounted by the money market account are $((\mathcal{F}_t), \mathbf{P})$ -martingales, that is, where \mathbf{P} is an equivalent probability measure that uses the money market account as numeraire.³ Such an equivalent measure is called a risk neutral measure, because under this probability measure the investors are indifferent between investing in the money market account or in any other asset. There are different scenarios under which the transition from the physical to the equivalent (or risk neutral) probability measure can usually be accomplished.

We present a mathematical framework that will embody essentially all models used throughout this entry. Nevertheless, more general frameworks can be considered. On our probability space Π we assume that there exists an R^J -valued Markov process $X_t = (X_{1,t}, \dots, X_{J,t})'$ or background process, that represents J economy-wide variables, either state (observable) or latent (not observable).⁴ There also exist I counting processes, $N_{i,t}$, $i = 1, \dots, I$, initialized at 0, that represent the default processes of the I firms in the economy such that the default of the i th firm occurs when $N_{i,t}$ jumps from 0 to 1. $(\mathcal{G}_{X,t})$ and $(\mathcal{G}_{i,t})$, where $\mathcal{G}_{X,t} = \sigma(X_s, 0 \leq s \leq t)$ and $\mathcal{G}_{i,t} = \sigma(N_{i,t}, 0 \leq s \leq t)$, represent the filtrations

generated by X_t and $N_{i,t}$ respectively. The filtration $(\mathcal{G}_{X,t})$ represents information about the development of general market variables and all the background information, whereas $(\mathcal{G}_{i,t})$ only contains information about the default status of firm i .

The filtration (\mathcal{F}_t) contains the information generated by both the information contained in the state variables and the default processes:

$$(\mathcal{F}_t) = (\mathcal{G}_{X,t}) \vee (\mathcal{G}_{1,t}) \vee \dots \vee (\mathcal{G}_{I,t}) \quad (2)$$

We also define the filtrations $(\mathcal{F}_{i,t})$, $i = 1, \dots, I$, as

$$(\mathcal{F}_{i,t}) = (\mathcal{G}_{X,t}) \vee (\mathcal{G}_{i,t}) \quad (3)$$

which only accumulate the information generated by the state variables and the default status of each firm.

Poisson and Cox Processes

Poisson processes provide a convenient way of modeling default arrival risk in intensity-based default risk models.⁵ In contrast to structural models, the time of default in intensity models is not determined via the value of the firm, but instead is taken to be the first jump of a point process (for example, a Poisson process). The parameters governing the default intensity (associated with the probability measure \mathbf{P}) are inferred from market data.

First, we recall the formal definition of Poisson and Cox processes. Consider an increasing sequence of stopping times $(\tau_h < \tau_{h+1})$. We define a counting process associated with that sequence as a stochastic process N_t given by

$$N_t = \sum_h \mathbf{1}_{\{\tau_h \leq t\}} \quad (4)$$

A (homogeneous) Poisson process with intensity $\lambda > 0$ is a counting process whose increments are independent and satisfy

$$\mathbf{P}[N_t - N_s = n] = \frac{1}{n!} (t - s)^n \lambda^n \exp(-(t - s)\lambda) \quad (5)$$

for $0 \leq s \leq t$, that is, the increments $N_t - N_s$ are independent and have a Poisson distribution with parameter $\lambda(t - s)$ for $s \leq t$.

So far, we have considered only the case of homogeneous Poisson processes where the default intensity is a constant parameter λ , but we can easily generalize it allowing the default intensity to be time dependent $\lambda_t = \lambda(t)$, in which case we would talk about unhomogeneous Poisson processes.

If we consider stochastic default intensities, the Poisson process would be called a Cox process. For example, we can assume λ_t follows a diffusion process of the form

$$d\lambda_t = \mu(t, \lambda_t)dt + \sigma(t, \lambda_t)dW_t \quad (6)$$

where W_t is a Brownian motion. We can also assume that the intensity is a function of a set of state variables (economic variables, interest rates, currencies, etc.) X_t , that is, $\lambda_t = \lambda(t, X_t)$.

The fundamental idea of the intensity-based framework is to model the default time as the first jump of a Poisson process. Thus, we define the default time to be

$$\tau = \inf \{t \in \mathbb{R}^+ \mid N_t > 0\} \quad (7)$$

The survival probabilities in this setup are given by

$$\mathbf{P}[N_t = 0] = \mathbf{P}[\tau > t] = E \left[\exp \left(- \int_0^t \lambda_s ds \right) \right] \quad (8)$$

The intensity, or hazard rate, is the conditional default arrival rate, given no default:

$$\lim_{h \rightarrow 0} \frac{\mathbf{P}[\tau \in (t, t+h] \mid \tau > t]}{h} = \frac{f(t)}{1 - F(t)} = \lambda_t \quad (9)$$

where

$$F(t) = \mathbf{P}[\tau \leq t] \quad (10)$$

and $f(t)$ is the density of F .

The functions $p(t, T) = \mathbf{P}[\tau \leq T \mid \tau > t]$ and $s(t, T) = \mathbf{P}[\tau > T \mid \tau > t]$ are the risk neutral default and survival probabilities from time t to time T respectively, where $0 \leq t \leq T$. Note

that $s(t, T) = 1 - p(t, T)$, and if we fix $t = 0$, then $p(0, T) = F(T)$.

The hazard or intensity rate λ_t is the central element of reduced form models, and represents the instantaneous default probability, that is, the (very) short-term default risk.

Pricing Building Blocks

This section reviews the pricing of risk-free and defaultable zero-coupon bonds, which together with the default/survival probabilities constitute the building blocks for pricing credit derivatives and defaultable instruments.

We assume a perfect and arbitrage-free capital market, where the money market account value process β_t is given by (1). Since our probability measure \mathbf{P} takes as numeraire the money market account process, the value of any NDP-asset discounted by the money market account follows an $((\mathcal{F}_t), \mathbf{P})$ -martingale. Using the previous property, the price at time t of a default-free zero coupon bond with maturity T and face value of 1 unit is given by

$$\begin{aligned} P(t, T) &= \beta_t E \left[\frac{P(T, T)}{\beta_T} \mid \mathcal{F}_t \right] \\ &= E \left[\exp \left(- \int_t^T r_s ds \right) \mid \mathcal{F}_t \right] \end{aligned} \quad (11)$$

From the previous section we know that the survival probability $s(t, T)$ in the risk-neutral measure can be expressed as

$$\begin{aligned} s(t, T) &= \mathbf{P}[\tau > T \mid \tau > t] \\ &= E \left[\exp \left(- \int_t^T \lambda_s ds \right) \mid \mathcal{F}_t \right] \end{aligned} \quad (12)$$

Consider a defaultable zero coupon bond issued by firm i with maturity T and face value of M units that, in case of default at time $\tau < T$, generates a recovery payment of R_τ units. R_t is an (\mathcal{F}_t) -adapted stochastic process, with $R_t = 0$ for all $t > T$.⁶ The price of the defaultable coupon bond at time t , ($0 \leq t \leq T$), is given

by

$$\begin{aligned} Q(t, T) &= \beta_t E \left[\frac{Q(T, T)}{\beta_T} \mid \mathcal{F}_t \right] \\ &= \beta_t E \left[\frac{M \mathbf{1}_{\{\tau > T\}}}{\beta_T} \mid \mathcal{F}_t \right] + \beta_t E \left[\frac{R_\tau}{\beta_\tau} \mid \mathcal{F}_t \right] \end{aligned} \quad (13)$$

which can be expressed as⁷

$$\begin{aligned} Q(t, T) &= E \left[\exp \left(- \int_t^T (r_s + \lambda_s) ds \right) M \mid \mathcal{F}_t \right] + \\ &E \left[\int_t^T R_s \lambda_s \exp \left(- \int_t^s (r_u + \lambda_u) du \right) ds \mid \mathcal{F}_t \right] \end{aligned} \quad (14)$$

assuming $\tau > t$ and all the technical conditions that ensure that the expectations are finite.⁸ This expression has to be evaluated considering the treatment of the recovery payment and any other assumptions about the correlations between interest rates, intensities, and recoveries. The first term represents the expected discounted value of the payment of M units at time T , taking into account the possibility that the firm may default and the M units not received, through the inclusion of the hazard or intensity rate (instantaneous probability of default) in the discount rate. The second term represents the expected discounted value of the recovery payment using the risk-free rate plus the intensity rate as discount factor. The first integral in the second term of the previous expression, from t to T , makes reference to the fact that default can happen at any time between t and T . Thus, for each $s \in (t, T]$, we discount the value of the recovery rate R_s times the instantaneous probability of default at time s given that no default has occurred before, which is given by the intensity λ_s .

Recovery Rates

Recovery rates refer to how we model, after a firm defaults, the value that a debt instrument has left.⁹ In terms of the recovery rate parametrization, three main specifications have

been adopted in the literature. The first one considers that the recovery rate is an exogenous fraction of the face value of the defaultable bond (recovery of face value, RFV).¹⁰ Jarrow and Turnbull (1997) consider the recovery rate to be an exogenous fraction of the value of an equivalent default-free bond (recovery of treasury, RT). Finally, Duffie and Singleton (1999a) fix a recovery rate equal to an exogenous fraction of the market value of the bond just before default (recovery of market value, RMV).

The RMV specification has gained a great deal of attention in the literature thanks to, among others, Duffie and Singleton (1999a). Consider a zero-coupon defaultable bond, which pays M at maturity T if there is no default prior to maturity and whose payoff in case of default is modeled according to the RMV assumption. They show that this bond can be priced as if it were a default-free zero-coupon bond, by replacing the usual short-term interest rate process r_t with a default-adjusted short rate process $\pi_t = r_t + \lambda_t L_t$. L_t is the expected loss rate in the market value if default were to occur at time t , conditional on the information available up to time t :

$$R_\tau = (1 - L_\tau)Q(\tau-, T) \tag{15}$$

$$Q(\tau-, T) = \lim_{\substack{s \rightarrow \tau \\ s \leq \tau}} Q(s, T) \tag{16}$$

where τ is the default time, $Q(\tau-, T)$ the market price of the bond just before default, and R_τ the value of the defaulted bond. Duffie and Singleton (1999a) show that (14) can be expressed as

$$Q(t, T) = E \left[\exp \left(- \int_t^T \pi_s ds \right) M \mid \mathcal{F}_t \right] \tag{17}$$

This expression shows that discounting at the adjusted rate π_t accounts for both the probability and the timing of default, and for the effect of losses at default. But the main advantage of the previous pricing formula is that, if the mean loss rate $\lambda_t L_t$ does not depend on the value of the defaultable bond, we can apply well-known term structure processes to model π_t instead of r_t to

price defaultable debt. One of the main drawbacks of this approach is that since $\lambda_t L_t$ appears multiplied in π_t , in order to be able to estimate λ_t and L_t separately using data of defaultable instruments, it is not enough to know defaultable bond prices alone. We would need to have available a collection of bonds that share some, but not all, default characteristics, or derivative securities whose payoffs depend, in different ways, on λ_t and L_t . In case λ_t and L_t are not separable, we shall have to model the product $\lambda_t L_t$ (which represents the short-term credit spread).¹¹ This identification problem is the reason why most of the empirical work that tries to estimate the default intensity process from defaultable bond data uses an exogenously given constant, that is, $L_t = L$ for all t , recovery rate.¹²

The previous valuation formula allows one to introduce dependencies between short-term interest rates, default intensities, and recovery rates (via state variables, for example).

From a pricing point of view, the above pricing formula allows us to include the case in which, as is often seen in practice after a default takes place, a firm reorganizes itself and continues with its activity. If we assume that after each possible default the firm is reorganized and the bondholders lose a fraction L_t of the predefault bond's market value, Giesecke (2002a) shows that letting L_t be a constant, that is, $L_t = L$ for all t , the price of a default risky zero-coupon bond is, as in the case with no reorganization, given by (17).

Another advantage of this framework is that it allows one to consider liquidity risk by introducing a stochastic process l_t as a liquidity spread in the adjusted discount process π_t ; that is, $\pi_t = r_t + \lambda_t L_t + l_t$.

SINGLE ENTITY

The aim of this section is to develop some tools in the modeling of intensity processes, in order to build the models for *default correlation*. In case we consider a deterministic specification

for default intensities, it is natural to think of time dependent intensities, in which $\lambda_t = \lambda(t)$, where $\lambda(t)$ is usually modeled as either a constant, linear, or quadratic polynomial of the time to maturity.¹³

The treatment of default-free interest rates, the recovery rate, and the intensity process differentiates each intensity model.

It is interesting to note that the difference between the pricing formulas of default-free zero-coupon bonds and survival probabilities in the intensity approach lies in the discount rate:

$$P(0, t) = E \left[\exp \left(- \int_0^t r_s ds \right) \right] \quad (18)$$

$$s(0, t) = E \left[\exp \left(- \int_0^t \lambda_s ds \right) \right] \quad (19)$$

This analogy between intensity-based default risk models and interest rate models allows us to apply well-known short-rate term models to the modeling of default intensities.

Schönbucher (2003) enumerates several characteristics that an ideal specification of the interest rate r_t and the default intensity λ_t should have. First, both r_t and λ_t should be stochastic. Second, the dynamics of r_t and λ_t should be rich enough to include correlation between them. Third, it is desirable to have processes for r_t and λ_t that remain positive at all times. And finally, the easier the pricing of the pricing building blocks, the better.

We start with a general framework, making use of the Markov process $X_t = (X_{1,t}, \dots, X_{J,t})'$, which represents J state variables. The most general process for X_t that we shall consider is called a basic affine process, which is an example of an affine jump diffusion given by

$$dX_{j,t} = \kappa_j (\theta_j - X_{j,t}) dt + \sigma_j \sqrt{X_{j,t}} dW_{j,t} + dq_{j,t} \quad (20)$$

for $j = 1, \dots, J$, where $W_{j,t}$ is an $((\mathcal{F}_t), \mathbf{P})$ -Brownian motion. κ_j and θ_j represent the mean reversion rate and level of the process, and σ_j is a constant affecting the volatility of the process. $dq_{j,t}$ denotes any jump that occurs at time t of

a pure-jump process $q_{j,t}$, independent of $W_{j,t}$, whose jump sizes are exponentially distributed with mean μ_j and whose jump times are independent Poisson random variables with intensity of arrival γ_j (jump times and jump sizes are also independent). By modeling the jump size as an exponential random variable, we restrict the jumps to be positive. This process is called a basic affine process with parameters $(\kappa_j, \theta_j, \sigma_j, \mu_j, \gamma_j)$.¹⁴

Making r_t and λ_t dependent on a set of common stochastic factors X_t , one can introduce randomness and correlation in the processes of r_t and λ_t . Moreover, if we use basic affine processes for the common factors X_t , we can make use of the following results, which will yield closed-form solutions for the building blocks we examined in the previous section.¹⁵

1. For any discount-rate function $\varphi : R^J \rightarrow R$ and any function $g : R^J \rightarrow R$, if X_t is a Markov process (which holds in the case of basic affine process), then

$$E \left[\exp \left(- \int_s^t \varphi(X_u) du \right) g(X_t) \mid \mathcal{F}_s \right] = H(X_s) \quad (21)$$

for $0 \leq s \leq t$ and for some function $H : R^J \rightarrow R$.

2. Defining an affine function as constant plus linear, if $\varphi(x)$ and $g(x)$ are affine functions ($\varphi(x) = a_0 + a_1 x_1 + \dots + a_J x_J$ and $g(x) = b_0 + b_1 x_1 + \dots + b_J x_J$) then, as shown by Duffie, Pan, and Singleton (2000), if X_t is an affine jump-diffusion process, it is verified that $H(X_s)$ can be expressed in closed form by

$$H(X_s) = \exp(\alpha(s, t) + \theta(s, t) \cdot X_s) \quad (22)$$

for some coefficients $\alpha(s, t), \theta_1(s, t), \dots, \theta_J(s, t)$ which are functions, also in closed form, of the parameters of the model.¹⁶

Observing that our pricing building blocks $P(t, T)$, $s(t, T)$ and $Q(t, T)$ are special cases of the previous expressions, one realizes the gains in terms of tractability achieved by the use of

affine processes in the modelling of the default term structure.¹⁷ In order to make use of this tractability the state variables X_t should follow affine processes, and the specification for the risk-adjusted rate π_t should be an affine function of the state variables.

Consider the case in which the $X_{1,t}, \dots, X_{J,t}$ follow (20). If we eliminate the jump component from the process of $X_{j,t}$

$$dX_{j,t} = \kappa_j (\theta_j - X_{j,t}) dt + \sigma_j \sqrt{X_{j,t}} dW_{j,t} \quad (23)$$

we obtain the CIR process, and eliminating the square root of $X_{j,t}$

$$dX_{j,t} = \kappa_j (\theta_j - X_{j,t}) dt + \sigma_j dW_{j,t} \quad (24)$$

we end up with a Vasicek model.

Various reduced-form models differ from each other in their choices of the state variables and the processes they follow. In the models we consider below, the intensity and interest rate are linear, and therefore affine, functions of X_t , where X_t are basic affine processes.¹⁸

One can consider expressions for r_t and λ_t of the general form

$$r_t = a_{0,r}(t) + a_{1,r}(t) X_{1,t} + \dots + a_{J,r}(t) X_{J,t} \quad (25)$$

$$\lambda_t = a_{0,\lambda}(t) + a_{1,\lambda}(t) X_{1,t} + \dots + a_{J,\lambda}(t) X_{J,t} \quad (26)$$

for some deterministic (possibly time-dependent) coefficients $a_{j,r}$ and $a_{j,\lambda}$, $j = 1, \dots, J$. This type of model allows us to treat r_t and λ_t as stochastic processes, to introduce correlations between them, and to have analytically tractable expressions for pricing the building blocks. A simple example could be

$$dr_t = \kappa_r (\theta_r - r_t) dt + \sigma_r \sqrt{r_t} dW_{r,t} \quad (27)$$

$$d\lambda_t = \kappa_\lambda (\theta_\lambda - \lambda_t) dt + \sigma_\lambda \sqrt{\lambda_t} dW_{\lambda,t} + dq_{\lambda,t} \quad (28)$$

$$dW_{r,t} dW_{\lambda,t} = \rho dt \quad (29)$$

in which the state variables are r_t and λ_t themselves, whose Brownian motions are correlated.

Duffie (2005) presents an extensive review of the use of affine processes for credit risk modeling using intensity models, and applies such models to price different credit derivatives (credit default swaps, credit guarantees, spread options, lines of credit, and ratings-based step-up bonds.)

Default Times Simulation

Letting U be a uniform (0,1) random variable independent of $(\mathcal{G}_{X,t})$, the time of default is defined by

$$\tau = \inf \left\{ t > 0 \mid \exp \left(- \int_0^t \lambda_s ds \right) \leq U \right\} \quad (30)$$

Equivalently, we can let η be an exponentially distributed random variable with parameter 1 and independent of $(\mathcal{G}_{X,t})$ and define the default time as

$$\tau = \inf \left\{ t > 0 \mid \int_0^t \lambda_s ds \geq \eta \right\} \quad (31)$$

Once we have specified and calibrated the dynamics of λ_t , we can easily simulate default times using a simple procedure based on the two previous definitions. First, we simulate a realization u of a uniform $[0, 1]$ random variable U and choose τ such that $\exp(-\int_0^\tau \lambda_s ds) = u$. Equally, we can simulate a random variable η exponentially distributed with parameter 1 and fix τ such that $\int_0^\tau \lambda_s ds = \eta$.

DEFAULT CORRELATION

This section reviews the different approaches to model the default dependence between firms in the reduced-form approach. With the tools provided in the previous section we can calculate the survival or default probability of a given firm in a given time interval. The next natural question to ask ourselves concerns the default or survival probability of more than one firm. If we are currently at time t ($0 \leq t \leq T$) and no default has occurred so far, what is the probability

that $n \geq 1$ different firms default before time T ? or, what is the probability that they all survive until time T ?

Schönbucher (2003), again, points out some properties that any good approach to model dependent defaults should verify. First, the model must be able to produce default correlations of a realistic magnitude. Second, it has to do it by keeping the number of parameters introduced to describe the dependence structure under control, without growing dramatically with the number of firms. Third, it should be a dynamic model, able to model the number of defaults as well as the timing of defaults. Fourth, since it is clear from the default history that there are periods in which defaults may cluster, the model should be capable of reproducing these periods. And fifth, the easier the calibration and implementation of the model, the better.

We can distinguish three different approaches to model default correlation in the literature of intensity credit risk modeling. The first approach introduces correlation in the firms' default intensities making them dependent on a set of common variables X_t and on a firm specific factor. These models have received the name of conditionally independent defaults (CID) models, because conditioned to the realization of the state variables X_t , the firm's default intensities are independent as are the default times that they generate. Apparently, the main drawback of these models is that they do not generate sufficiently high default correlations. However, Yu (2002a) indicates that this is not a problem of the model per se, but rather an indication of the lack of sophistication in the choice of the state variables.

Two direct extensions of the CID approach try to introduce more default correlation in the models. One is the possibility of joint jumps in the default intensities (Duffie and Singleton 1999b) and the other is the possibility of default-event triggers that cause joint defaults (Duffie and Singleton 1999b, Kijima 2000, and Kijima and Muromachi 2000).

The second approach to model default correlation, *contagion models*, relies on the works by Davis and Lo (1999) and Jarrow and Yu (2001). It is based on the idea of default contagion in which, when a firm defaults, the default intensities of related firms jump upwards. In these models default dependencies arise from direct links between firms. The default of one firm increases the default probabilities of related firms, which might even trigger the default of some of them.

The last approach to model default correlation makes use of *copula functions*. A copula is a function that links univariate marginal distributions to the joint multivariate distribution with auxiliary correlating variables. To estimate a joint probability distribution of default times, we can start by estimating the marginal probability distributions of individual defaults, and then transform these marginal estimates into the joint distribution using a copula function. Copula functions take as inputs the individual probabilities and transform them into joint probabilities, such that the dependence structure is completely introduced by the copula.

Measures of Default Correlation

The complete specification of the default correlation will be given by the joint distribution of default times. Nevertheless, we can specify some other measures of default correlation. Consider two firms A and B that have not defaulted before time t ($0 \leq t \leq T$). We denote the probabilities that firms A and B will default in the time interval $[t, T]$ by p_A and p_B respectively. Denote p_{AB} the probability of both firms defaulting before T , and τ_A and τ_B the default times of each firm. The linear correlation coefficient between the default indicator random variables $\mathbf{1}_A = \mathbf{1}_{\{\tau_A \leq T\}}$ and $\mathbf{1}_B = \mathbf{1}_{\{\tau_B \leq T\}}$ is given by

$$\rho(\mathbf{1}_{\{\tau_A \leq T\}}, \mathbf{1}_{\{\tau_B \leq T\}}) = \frac{p_{AB} - p_A p_B}{\sqrt{p_A(1-p_A)p_B(1-p_B)}} \quad (32)$$

In the same way we can define the linear correlation of the random variables $\mathbf{1}_{\{\tau_A > T\}}$ and $\mathbf{1}_{\{\tau_B > T\}}$. Another measure of default dependence between firms is the linear correlation between the random variables τ_A and τ_B , $\rho(\tau_A, \tau_B)$.

The conclusions extracted from the comparison of linear default correlations should be viewed with caution because they are covariance-based and hence they are only the natural dependence measures for joint elliptical random variables.¹⁹ Default times, default events, and survival events are not elliptical random variables, and hence these measures can lead to severe misinterpretations of the true default correlation structure.²⁰

The previous correlation coefficients, when estimated via a risk neutral intensity model, are based on the risk neutral measure. However, when we calculate the correlation coefficients using empirical default events, the correlation coefficients are obtained under the physical measure. Jarrow, Lando, and Yu (2001) and Yu (2002a, b) provide a procedure for computing physical default correlation through the use of risk neutral intensities.

Conditionally Independent Default Models

From now on, we consider $i = 1, \dots, I$ different firms and denote by $\lambda_{i,t}$ and τ_i their default intensities and default times respectively.

In CID models, firms' default intensities are independent once we fix the realization of the state variables X_t . The default correlation is introduced through the dependence of each firm's intensity on the random vector X_t . A firm-specific factor of stochasticity $\lambda_{i,t}^*$, independent across firms, completes the specification of each firm's default intensity:

$$\lambda_{i,t} = a_{0,\lambda_i} + a_{1,\lambda_i} X_{1,t} + \dots + a_{J,\lambda_i} X_{J,t} + \lambda_{i,t}^* \tag{33}$$

where a_{j,λ_i} are some deterministic coefficients, for $j = 1, \dots, J$ and $i = 1, \dots, I$.²¹

Since default times are continuously distributed, this specification implies that the probability of having two or more simultaneous defaults is zero.

Let us consider an example of a CID model based on Duffee (1999). The default-free interest rate is given by

$$r_t = a_{r,0} + X_{1,t} + X_{2,t} \tag{34}$$

where $a_{r,0}$ is a constant coefficient, and $X_{1,t}$ and $X_{2,t}$ are two latent factors (unobservable, interpreted as the slope and level of the default-free yield curve). After having estimated the latent factors $X_{1,t}$ and $X_{2,t}$ from default-free bond data, Duffee (1999) uses them to model the intensity process of each firm i as

$$\lambda_{i,t} = a_{0,\lambda_i} + a_{1,\lambda_i} (X_{1,t} - \bar{X}_1) + a_{2,\lambda_i} (X_{2,t} - \bar{X}_2) + \lambda_{i,t}^* \tag{35}$$

$$d\lambda_{i,t}^* = \kappa_i (\theta_i - \lambda_{i,t}^*) dt + \sigma_i \sqrt{\lambda_{i,t}^*} dW_{i,t} \tag{36}$$

where $W_{1,t}, \dots, W_{I,t}$ are independent Brownian motions, a_{0,λ_i} , a_{1,λ_i} , and a_{2,λ_i} are constant coefficients, and \bar{X}_1 and \bar{X}_2 are the sample means of $X_{1,t}$ and $X_{2,t}$.

The intensity of each firm i depends on the two common latent factors $X_{1,t}$ and $X_{2,t}$, and on an idiosyncratic factor $\lambda_{i,t}^*$, independent across firms. The coefficients a_{0,λ_i} , a_{1,λ_i} , a_{2,λ_i} , κ_i , θ_i and σ_i are different for each firm. In Duffee's model, $\lambda_{i,t}^*$ captures the stochasticity of intensities and the coefficients a_{1,λ_i} and a_{2,λ_i} , $i = 1, \dots, I$, capture the correlations between intensities themselves, and between intensities and interest rates.

Duffee (1999), Zhang (2003), Driessen (2005), and Elizalde (2005b) propose, and estimate, different CID models.²²

The literature on credit risk correlation has criticized the CID approach, arguing that it generates low levels of default correlation when compared with empirical default correlations. However, Yu (2002a) suggests that this apparent low correlation is not a problem of the approach itself but a problem of the choice of state or latent variables, owing to the

inability of a limited set of state variables to fully capture the dynamics of changes in default intensities. In order to achieve the level of correlation seen in empirical data, a CID model must include among the state variables the evolution of the stock market, corporate and default-free bond markets, as well as various industry factors.

According to Yu, the problem of low correlation in Duffee's model may arise because of the insufficient specification of the common factor structure, which may not capture all the sources of common variation in the model, leaving them to the idiosyncratic component, which in turn would not be independent across firms. In fact, Duffee finds that idiosyncratic factors are statistically significant and correlated across firms. As long as the firms' credit risk depend on common factors different from the interest rate factors, Duffee's specification is not able to capture all the correlation between firms' default probabilities. Xie, Wu, and Shi (2004) estimate Duffee's model for a sample of U.S. corporate bonds and perform a careful analysis of the model pricing errors. A principal component analysis reveals that the first factor explains more than 90% of the variation of pricing errors. Regressing bond pricing errors with respect to several macroeconomic variables, they find that returns on the S&P 500 index explain around 30% of their variations. Therefore, Duffee's model leaves out some important aggregate factors that affect all bonds.

Driessen (2005) proposes a model in which the firms' hazard rates are a linear function of two common factors, two factors derived from the term structure of interest rates, a firm idiosyncratic factor, and a liquidity factor. Yu also examines the model of Driessen (2005), finding that the inclusion of two new common factors elevates the default correlation.

Finally, Elizalde (2005b) shows that any firm's credit risk is, to a very large extent, driven by common risk factors affecting all firms. The study decomposes the credit risk of a sample of corporate bonds (14 U.S. firms, 2001–2003)

into different unobservable risk factors. A single common factor accounts for more than 50% of all (but two) of the firms' credit risk levels, with an average of 68% across firms. Such factor represents the credit risk levels underlying the U.S. economy and is strongly correlated with main U.S. stock indexes. When three common factors are considered (two of them coming from the term structure of interest rates), the model explains an average of 72% of the firms' credit risk.²³

Default Times Simulation

In the CID approach, to simulate default times we proceed as we did in the single entity case. Once we know the realization of the state variables X_t , we simulate a set of I independent unit exponential random variables η_1, \dots, η_I , which are also independent of $(\mathcal{G}_{X,t})$. The default time of each firm $i = 1, \dots, I$ is defined by

$$\tau_i = \inf \left\{ t > 0 \mid \int_0^t \lambda_{i,s} ds \geq \eta_i \right\} \quad (37)$$

Thus, once we have simulated η_i , τ_i will be such that

$$\int_0^{\tau_i} \lambda_{i,s} ds = \eta_i \quad (38)$$

Joint Jumps/Joint Defaults Duffie and Singleton (1999b) proposed two ways out of the low correlation problem. One is the possibility of joint jumps in the default intensities, and the other is the possibility of default-event triggers that cause joint defaults.²⁴

Duffie and Singleton develop an approach in which firms experience correlated jumps in their default intensities. Assume that the default intensity of each firm follows the following process:

$$d\lambda_{i,t} = \kappa_i (\theta_i - \lambda_{i,t}) dt + dq_{i,t} \quad (39)$$

which consists of a deterministic mean reversion process plus a pure jump process $q_{i,t}$, whose intensity of arrival is distributed as a Poisson random variable with parameter γ_i and

whose jump size follows an exponential random variable with mean μ (equal for all firms $i = 1, \dots, I$).²⁵ Duffie and Singleton introduce correlation to the firm's jump processes, keeping unchanged the characteristics of the individual intensities. They postulate that each firm's jump component consists of two kinds of jumps, joint jumps and idiosyncratic jumps. The joint jump process has a Poisson intensity γ_c and an exponentially distributed size with mean μ . Individual default intensities experience a joint jump with probability p_i . That is, a firm suffers a joint jump with Poisson intensity of arrival of $p_i\gamma_c$. In order to keep the total jump in each firm's default intensity with intensity of arrival γ_i and size μ , the idiosyncratic jump (independent across firms) is set to have an exponentially distributed size μ and intensity of arrival h_i , such that $\gamma_i = p_i\gamma_c + h_i$.

Note that if $p_i = 0$ the jumps are only idiosyncratic jumps, implying that default intensities and hence default times are independent across firms. If $p_i = 1$ and $h_i = 0$ all firms have the same jump intensity, which does not mean that default times are perfectly correlated, since the size of the jump is independent across firms. Only if we additionally assume that μ goes to infinity we obtain identical default times.

The second alternative considers the possibility of simultaneous defaults triggered by common credit events, at which several obligors can default with positive probability. Imagine there exist $m = 1, \dots, M$ common credit events, each one modeled as a Poisson process with intensity $\lambda_{m,t}^c$. Given the occurrence of a credit event m at time t , each firm i defaults with probability $p_{i,m,t}$. If, given the occurrence of a common shock, the firm's default probability is less than one, this common shock is called nonfatal shock, whereas if this probability is one, the common shock is called fatal shock. In addition to the common credit events, each entity can experience default through an idiosyncratic Poisson process with intensity $\lambda_{i,t}^*$, which is independent across firms. Therefore, the total

intensity of firm i is given by

$$\lambda_{i,t} = \lambda_{i,t}^* + \sum_{m=1}^M p_{i,m,t} \lambda_{m,t}^c \quad (40)$$

Consider a simplified version of this setting with two firms, constant idiosyncratic intensities λ_1^* and λ_2^* , and one common and fatal event with constant intensity λ^c . In this case firm i 's survival probability is given by

$$s_i(t, T) = \exp\left(-\left(\lambda_i^* + \lambda^c\right)(T - t)\right) \quad (41)$$

Denoting by $s(t; T_1, T_2)$ the joint survival probability, given no default until time t , that firm 1 does not default before time T_1 and firm 2 does not default before time T_2 , then

$$\begin{aligned} s(t; T_1, T_2) &= \exp(-\lambda_1^*(T_1 - t) - \lambda_2^*(T_2 - t) \\ &\quad - \lambda^c \max\{T_1 - t, T_2 - t\}) = \\ &= \exp(-(\lambda_1^* + \lambda^c)(T_1 - t) \\ &\quad - (\lambda_2^* + \lambda^c)(T_2 - t) + \lambda^c \\ &\quad \min\{T_1 - t, T_2 - t\}) \end{aligned} \quad (42)$$

which can be expressed as

$$\begin{aligned} s(t; T_1, T_2) &= s_1(t, T) s_2(t, T) \\ &\quad \min\{\exp(\lambda^c(T_1 - t)), \exp(\lambda^c(T_2 - t))\} \end{aligned} \quad (43)$$

This expression for the joint survival probability explicitly includes individual survival probabilities and a term that introduces the dependence structure. This is the approach followed by copula functions, which couple marginal probabilities into joint probabilities. In fact, the above example is a special case of copula function, called Marshall-Olkin copula.

The relationship between joint survival and default probabilities is given by

$$\begin{aligned} s(t; T_1, T_2) &= 1 - p_1(t, T_1) - p_2(t, T_2) \\ &\quad + p(t; T_1, T_2) \end{aligned} \quad (44)$$

where $p(t; T_1, T_2)$ represents the joint default probability, given no default until time t , that firm 1 defaults before time T_1 and firm 2

defaults before time T_2 . Obviously the case with multiple common shocks is more troublesome in terms of notation and calibration because, for every possible common credit event, an intensity must be specified and calibrated.²⁶

Duffie and Singleton (1999b) propose algorithms to simulate default times within these two frameworks. The criticisms that the joint credit event approach has received stem from the fact that it is unrealistic that several firms default at exactly the same time, and also from the fact that after a common credit event that makes some obligors default, the intensity of other related obligors that do not default does not change at all.

Although theoretically appealing, the main drawback of these two last models has to do with their calibration and implementation. To the best of my knowledge there is not a single paper that carries out an empirical calibration and implementation of a model like the ones presented in this section. The same applies to the contagion models presented in the next section.

Contagion Mechanisms

Contagion models take CID models one step further, introducing into the model two empirical facts: that the default of one firm can trigger the default of other related firms and that default times tend to concentrate in certain periods of time, in which the default probability of all firms is increased. The last model examined in the previous section (joint credit events) differs from contagion mechanisms in that if an obligor does not experience a default, its intensity does not change due to the default of any related obligor. The literature of default contagion includes two approaches: the infectious defaults model of Davis and Lo (1999), and the model proposed by Jarrow and Yu (2001), which we shall refer to as the propensity model. The main issues to be resolved concerning these two models are associated with difficulties in their calibration to market prices.

The Davis-Lo Infectious Defaults Model

The model developed by Davis and Lo (1999) has two versions, a static version that only considers the number of defaults in a given time period,²⁷ and a dynamic version in which the timing of default is also incorporated.²⁸

In the dynamic version of the model, each firm has an initial hazard rate of $\lambda_{i,t}$, for $i = 1, \dots, I$, which can be constant, time dependent, or follow a CID model. When a default occurs, the default intensity of all remaining firms is increased by a factor $a > 1$, called the enhancement factor, to $a\lambda_{i,t}$. This augmented intensity remains for an exponentially distributed period of time, after which the enhancement factor disappears ($a = 1$). During the period of augmented intensity, the default probabilities of all firms increase, reflecting the risk of default contagion.

The Jarrow-Yu Propensity Model

In order to account for the clustering of default in specific periods, Jarrow and Yu (2001) extend CID models to account for counterparty risk: the risk that the default of a firm may increase the default probability of other firms with which it has commercial or financial relationships. This allows them to introduce extra-default dependence in CID models to account for *default clustering*. In a first attempt, Jarrow and Yu assume that the default intensity of a firm depends on the status (default/not default) of the rest of the firms (symmetric dependence). However, symmetric dependence introduces a circularity in the model, which they refer to as looping defaults, which makes it extremely difficult and troublesome to construct and derive the joint distribution of default times.

Jarrow and Yu restrict the structure of the model to avoid the problem of looping defaults. They distinguish between primary firms ($1, \dots, K$) and secondary firms ($K + 1, \dots, I$). First, they derive the default intensity of primary firms, using a CID model. The primary

firm intensities $\lambda_{1,t}, \dots, \lambda_{K,t}$ are $(\mathcal{G}_{X,t})$ -adapted and do not depend on the default status of any other firm. If a primary firm defaults, this increases the default intensities of secondary firms, but not the other way around (asymmetric dependence). Thus, secondary firms' default intensities are given by

$$\lambda_{i,t} = \hat{\lambda}_{i,t} + \sum_{j=1}^K a_{i,t}^j \mathbf{1}_{\{\tau_j \leq t\}} \quad (45)$$

for $i = K + 1, \dots, I$ and $j = 1, \dots, K$, where $\hat{\lambda}_{i,t}$ and $a_{i,t}^j$ are $(\mathcal{G}_{X,t})$ -adapted. $\hat{\lambda}_{i,t}$ represents the part of secondary firm i 's hazard rate independent of the default status of other firms.

Default intensities of primary firms $\lambda_{1,t}, \dots, \lambda_{K,t}$ are $(\mathcal{G}_{X,t})$ -adapted, whereas default intensities of secondary firms $\lambda_{K+1,t}, \dots, \lambda_{I,t}$ are adapted with respect to the filtration $(\mathcal{G}_{X,t}) \vee (\mathcal{G}_{1,t}) \vee \dots \vee (\mathcal{G}_{K,t})$.

This model introduces a new source of default correlation between secondary firms, and also between primary and secondary firms, but it does not solve the drawbacks of low correlation between primary firms, which CID models apparently imply, because the setting for primary firms is, after all, only a CID model.²⁹

Default Times Simulation First we simulate the default times for the primary firms exactly as in the case of CID. Then, we simulate a set of $I-K$ independent unit exponential random variables $\eta_{K+1}, \dots, \eta_I$ (independent of $(\mathcal{G}_{X,t}) \vee (\mathcal{G}_{1,t}) \vee \dots \vee (\mathcal{G}_{K,t})$), and define the default time of each secondary firm $i = K + 1, \dots, I$ as

$$\tau_i = \inf \left\{ t > 0 \mid \int_0^t \lambda_{i,s} ds \geq \eta_i \right\} \quad (46)$$

Copulas

In CID and contagion models the specification of the individual intensities includes all the default dependence structure between firms. In contrast, the copula approach separates individual default probabilities from the credit risk dependence structure. The copula function

takes as inputs the marginal probabilities and introduces the dependence structure to generate joint probabilities.

Copulas were introduced in 1959 and have been extensively applied to model, among others, survival data in areas such as actuarial science.³⁰

In the rest of this section we review copula theory and its use in the credit risk literature. To make notation simple, assume we are at time $t = 0$ and take $s_i(t)$ and $p_i(t)$ (or $F_i(t)$) to be the survival and default probabilities, respectively, of firm $i = 1, \dots, I$ from time 0 to time $t > 0$. Then

$$F_i(t) = \mathbf{P}[\tau_i \leq t] = 1 - s_i(t) = 1 - \mathbf{P}[\tau_i > t] \quad (47)$$

where τ_i denotes the default time of firm i .

A copula function transforms marginal probabilities into joint probabilities. In case we model default times, the joint default probability is given by

$$\begin{aligned} F(t_1, \dots, t_I) &= \mathbf{P}[\tau_1 \leq t_1, \dots, \tau_I \leq t_I] \\ &= \mathbf{C}^d(F_1(t_1), \dots, F_I(t_I)) \end{aligned} \quad (48)$$

and if we model survival times, the joint survival probability takes the form

$$\begin{aligned} s(t_1, \dots, t_I) &= \mathbf{P}[\tau_1 > t_1, \dots, \tau_I > t_I] \\ &= \mathbf{C}^s(s_1(t_1), \dots, s_I(t_I)) \end{aligned} \quad (49)$$

where \mathbf{C}^d and \mathbf{C}^s are two different copulas.³¹

The copula function takes as inputs the marginal probabilities without considering how we have derived them. Thus, the intensity approach is not the only framework with which we can use copula functions to model the default dependence structure between firms. Any other approach to model marginal default probabilities, such as the structural approach, can use copula theory to model joint probabilities.

Description

An intuitive definition of a copula function is as follows:³²

Copula Function A function $C : [0, 1]^I \rightarrow [0, 1]$ is a copula if there are uniform random variables U_1, \dots, U_I taking values in $[0, 1]$ such that C is their joint distribution function.

A copula function C has uniform marginal distributions, that is,

$$C(1, \dots, 1, u_i, 1, \dots, 1) = u_i \quad (50)$$

for all $i = 1, \dots, I$ and $u_i \in [0, 1]$.

This definition is used, for example, by Schönbucher (2003).³³ The copula function C is the joint distribution of a set of I uniform random variables U_1, \dots, U_I . Copula functions allow one to separate the modeling of the marginal distribution functions from the modeling of the dependence structure. The choice of the copula does not constrain the choice of the marginal distributions. Sklar (1959) showed that any multivariate distribution function F can be written in the form of a copula function. The following theorem is known as Sklar's theorem:

Sklar's Theorem Let Y_1, \dots, Y_I be random variables with marginal distribution functions F_1, \dots, F_I and joint distribution function F . Then there exists an I -dimensional copula C such that $F(y_1, \dots, y_I) = C(F_1(y_1), \dots, F_I(y_I))$ for all (y_1, \dots, y_I) in R^I . Moreover, if each F_i is continuous, then the copula C is unique.

We shall consider the default times of each firm τ_1, \dots, τ_I as the marginal random variables whose joint distribution function will be determined by a copula function. If Y is a random variable with distribution function F , then the random variable U , defined as $U = F(Y)$, is a uniform $[0, 1]$ random variable. Denoting by t_i the realization of each τ_i ,³⁴

$$\begin{aligned} F(t_1, \dots, t_I) &= \mathbf{P}[\tau_1 \leq t_1, \dots, \tau_I \leq t_I] \\ &= C(F_1(t_1), \dots, F_I(t_I)) \end{aligned} \quad (51)$$

The marginal distribution of the default time τ_i will be given by

$$\begin{aligned} F_i(t_i) &= F(\infty, \dots, \infty, t_i, \infty, \dots, \infty) \\ &= \mathbf{P}[\tau_1 \leq \infty, \dots, \tau_i \leq t_i, \dots, \tau_I \leq \infty] = \\ &= C(F_1(\infty), \dots, F_i(t_i), \dots, F_I(\infty)) \\ &= C(1, \dots, F_i(t_i), \dots, 1) \end{aligned} \quad (52)$$

In the bivariate case, the relationship between the copula C^d and the survival copula C^s , which satisfies $s(t_1, t_2) = C^s(s_1(t_1), s_2(t_2))$, is given by³⁵

$$\begin{aligned} C^s(u_1, u_2) &= u_1 + u_2 - 1 \\ &+ C^d(1 - u_1, 1 - u_2) \end{aligned} \quad (53)$$

Nelsen (1999) points out that C^s is a copula and that it couples the joint survival function $s(\cdot, \dots, \cdot)$ to its univariate margins $s_1(\cdot), \dots, s_I(\cdot)$ in a manner completely analogous to the way in which a copula connects the joint distribution function $F(\cdot, \dots, \cdot)$ to its margins $F_1(\cdot), \dots, F_I(\cdot)$. When modeling credit risk using the copula framework we can specify a copula for either the default times or the survival times.

Measures of the Dependence Structure The dependence between the marginal distributions linked by a copula is characterized entirely by the choice of the copula. If C_1 and C_2 are two I -dimensional copula functions we say that C_1 is smaller than C_2 , denoted by $C_1 < C_2$, if $C_1(u) \leq C_2(u)$ for all $u \in [0, 1]^I$.

The Fréchet-Hoeffding copulas, C^- and C^+ , are two reference copulas given by³⁶

$$C^- = \max\{u_1 + \dots + u_I + 1 - I, 0\} \quad (54)$$

$$C^+ = \min\{u_1, \dots, u_I\} \quad (55)$$

satisfying $C^- < C < C^+$ for any copula C . However, this is a partial ordering in the sense that not every pair of copulas can be compared in this way.

In order to compare any two copulas, we would need an index to measure the dependence structure between two random variables introduced by the choice of the copula function. Linear (Pearson) correlation coefficient ρ is the

most used measure of dependence; however, it harbors several drawbacks, which makes it not very suitable to compare copula functions. For example, linear correlation depends not only on the copula but also on the marginal distributions.

We focus on four dependence measures that depend only on the copula function, not in the marginal distributions: Kendall's tau, Spearman's rho, and upper/lower tail dependence coefficients.

First, we introduce the concept of concordance:

Concordance Let (y_1, y_2) and (\hat{y}_1, \hat{y}_2) be two observations from a vector (Y_1, Y_2) of continuous random variables. Then, (y_1, y_2) and (\hat{y}_1, \hat{y}_2) are said to be concordant if $(y_1 - \hat{y}_1)(y_2 - \hat{y}_2) > 0$ and discordant if $(y_1 - \hat{y}_1)(y_2 - \hat{y}_2) < 0$.

Kendall's tau and Spearman's rho are two measures of concordance:

Kendall's Tau Let (Y_1, Y_2) and (\hat{Y}_1, \hat{Y}_2) be IID random vectors of continuous random variables with the same joint distribution function given by the copula \mathbf{C} (and with marginals F_1 and F_2). Then, Kendall's tau of the vector (Y_1, Y_2) (and thus of the copula \mathbf{C}) is defined as the probability of concordance minus the probability of discordance; that is,

$$\tau = \mathbf{P}[(Y_1 - \hat{Y}_1)(Y_2 - \hat{Y}_2) > 0] - \mathbf{P}[(Y_1 - \hat{Y}_1)(Y_2 - \hat{Y}_2) < 0] \quad (56)$$

Spearman's Rho Let (Y_1, Y_2) , (\hat{Y}_1, \hat{Y}_2) and $(\hat{\hat{Y}}_1, \hat{\hat{Y}}_2)$ be IID random vectors of continuous random variables with the same joint distribution function given by the copula \mathbf{C} (and with marginals F_1 and F_2). Then, Spearman's rho of the vector (Y_1, Y_2) (and thus of the copula \mathbf{C}) is defined as

$$\rho_S = 3(\mathbf{P}[(Y_1 - \hat{Y}_1)(Y_2 - \hat{\hat{Y}}_2) > 0] - \mathbf{P}[(Y_1 - \hat{Y}_1)(Y_2 - \hat{\hat{Y}}_2) < 0]) \quad (57)$$

Both Kendall's tau and Spearman's rho³⁷ take values in the interval $[0, 1]$ and can be defined in terms of the copula function by

$$\tau = 4 \iint_{[0,1]^2} \mathbf{C}(u, v) d\mathbf{C}(u, v) - 1 \quad (58)$$

$$\rho_S = 12 \iint_{[0,1]^2} uv d\mathbf{C}(u, v) - 3 = 12 \iint_{[0,1]^2} \mathbf{C}(u, v) dudv - 3 \quad (59)$$

The Fréchet-Hoeffding copulas take the two extreme values of Kendall's tau and Spearman's rho: If the copula of the vector (Y_1, Y_2) is \mathbf{C}^- then $\tau = \rho_S = -1$, and if it has copula \mathbf{C}^+ then $\tau = \rho_S = 1$. The product copula \mathbf{C}^P represents independent random variables, that is, if Y_1, \dots, Y_I are independent random variables, their copula is given by \mathbf{C}^P , such that $\mathbf{C}^P(u_1, \dots, u_I) = u_1 \dots u_I$. For a vector (Y_1, Y_2) of independent random variables, $\tau = \rho_S = 0$. Kendall's tau and Spearman's rho are equal for a given copula \mathbf{C} and its associated survival copula \mathbf{C}^s .

Kendall's tau and Spearman's rho are measures of global dependence. In contrast, tail dependence coefficients between two random variables (Y_1, Y_2) are local measures of dependence, as they refer to the level of dependence between extreme values, that is, values at the tails of the distributions $F_1(Y_1)$ and $F_2(Y_2)$.

Tail Dependence Let (Y_1, Y_2) be a random vector of continuous random variables with copula \mathbf{C} (and with marginals F_1 and F_2). Then, the coefficient of upper tail dependence of the vector (Y_1, Y_2) (and thus of the copula \mathbf{C}) is defined as

$$\lambda_U = \lim_{u \nearrow 1} \mathbf{P}[Y_1 > F_1^{-1}(u) \mid Y_2 > F_2^{-1}(u)] \quad (60)$$

where F_i^{-1} represents the inverse function of F_i , provided the limit exists. We say that the random vector (and thus the copula \mathbf{C}) has upper tail dependence if $\lambda_U > 0$. Similarly, the coefficient of lower tail dependence of the vector (Y_1, Y_2) (and thus

of the copula \mathbf{C} is defined as

$$\lambda_L = \lim_{u \searrow 0} \mathbf{P} [Y_1 < F_1^{-1}(u) \mid Y_2 < F_2^{-1}(u)] \quad (61)$$

We say that the random vector (and thus the copula \mathbf{C}) has lower tail dependence if $\lambda_L > 0$.

Upper (lower) tail dependence measures the probability that one component of the vector (Y_1, Y_2) is extremely large (small) given that the other is extremely large (small). As in the case of Kendall's tau and Spearman's rho, tail dependence is a copula property and can be expressed as³⁸

$$\lambda_U = \lim_{u \nearrow 1} \frac{1 + \mathbf{C}(u, u) - 2u}{1 - u} \quad (62)$$

$$\lambda_L = \lim_{u \searrow 0} \frac{\mathbf{C}(u, u)}{u} \quad (63)$$

The upper (lower) coefficient of tail dependence of the copula \mathbf{C} is the lower (upper) coefficient of tail dependence of its associated survival copula \mathbf{C}^s .

Consider the random vector (τ_1, τ_2) of default times for two firms. The coefficient of upper (lower) tail dependence represents the probability of long-term survival (immediate joint death). The existence of default clustering periods implies that a copula to model joint default (survival) probabilities should have lower (upper) tail dependence to capture those periods.

Examples of Copulas Here, we review some of the most used copulas in default risk modeling. The first two copulas, normal and Student t copulas, belong to the elliptical family of copulas. We also present the class of Archimedean copulas and the Marshall-Olkin copula.³⁹

1. Elliptical Copulas The I -dimensional normal copula with correlation matrix Σ is given by

$$\mathbf{C}(u_1, \dots, u_I) = \Phi_{\Sigma}^I(\Phi^{-1}(u_1), \dots, \Phi^{-1}(u_I)) \quad (64)$$

where Φ_{Σ}^I represents an I -dimensional normal distribution function with covariance matrix Σ ,

and Φ^{-1} denotes the inverse of the univariate standard normal distribution function.

Normal copulas are radially symmetric ($\lambda_U = \lambda_L$), tail independent ($\lambda_U = \lambda_L = 0$), and their concordance order depends on the linear correlation parameter ρ :

$$\mathbf{C}^- < \mathbf{C}_{\rho=-1} < \mathbf{C}_{\rho<0} < \mathbf{C}_{\rho=0} = \mathbf{C}^P < \mathbf{C}_{\rho>0} < \mathbf{C}_{\rho=1} = \mathbf{C}^+ \quad (65)$$

As with any other copula, the normal copula allows the use of any marginal distribution. We can express the linear correlation coefficients for a normal copula (ρ) in terms of both Kendall's tau (τ) and Spearman's rho (ρ_S) in the following way:

$$\rho = 2 \sin\left(\frac{\pi}{6} \rho_S\right) = \sin\left(\frac{\pi}{2} \tau\right) \quad (66)$$

Another elliptical copula is the t -copula. Letting X be a random vector distributed as an I -dimensional multivariate t -student with v degrees of freedom, mean vector μ (for $v > 1$) and covariance matrix $\frac{v}{v-2} \Sigma$ (for $v > 2$), we can express X as

$$X = \mu + \frac{\sqrt{v}}{\sqrt{S}} Z \quad (67)$$

where S is a random variable distributed as an χ^2 with v degrees of freedom and Z is an I -dimensional normal random vector, independent of S , with zero mean and linear correlation matrix Σ . The I -dimensional t -copula of X can be expressed as

$$\mathbf{C}(u_1, \dots, u_I) = t_{v,R}^I(t_v^{-1}(u_1), \dots, t_v^{-1}(u_I)) \quad (68)$$

where $t_{v,R}^I$ represents the distribution function of $\frac{\sqrt{v}}{\sqrt{S}} Y$, where Y is an I -dimensional normal random vector, independent of S , with zero mean and covariance matrix R . t_v^{-1} denotes the inverse of the univariate t -student distribution function with v degrees of freedom and $R_{ij} = \frac{\Sigma_{ij}}{\sqrt{\Sigma_{ii}\Sigma_{jj}}}$.

The t -copula is radially symmetric and exhibits tail dependence given by

$$\lambda_U = \lambda_L = 2 - 2t_{v+1} \left(\frac{(v+1)(1-\rho)}{(1+\rho)} \right)^{\frac{1}{2}} \quad (69)$$

where ρ is the linear correlation of the bivariate t-distribution.

2. Archimedean Copulas An I -dimensional Archimedean copula function \mathbf{C} is represented by

$$\mathbf{C}(u_1, \dots, u_I) = \phi^{-1}(\phi(u_1) + \dots + \phi(u_I)) \tag{70}$$

where the function $\phi : [0, 1] \rightarrow R^+$, called the generator of the copula, is invertible and satisfies $\phi'(u) < 0$, $\phi''(u) > 0$, $\phi(1) = 0$, $\phi(0) = \infty$. An Archimedean copula is entirely characterized by its generator function. Relevant Archimedean copulas are the Clayton, Frank, Gumbel, and Product copulas, whose generator functions are given by:

Copula	Generator $\phi(u)$
Clayton	$\frac{u^{-\theta}-1}{\theta}$ for $\theta \geq 0$
Frank	$-\ln \frac{e^{-\theta u}-1}{e^{-\theta}-1}$ for $\theta \in R \setminus \{0\}$
Gumbel	$(-\ln u)^\theta$ for $\theta \geq 1$
Product	$-\ln u$

The Clayton copula has lower tail dependence but not upper tail dependence. The Gumbel copula has upper tail dependence but not lower tail dependence. The Frank copula does not exhibit either upper or lower tail dependence.

Archimedean copulas allow for a great variety of different dependence structures, and the ones presented above are especially interesting because they are one-parameter copulas. In particular, the larger the parameter θ (in absolute value), the stronger the dependence structure. The Clayton, Frank, and Gumbel copulas are ordered in θ (i.e., $\mathbf{C}_{\theta_1} < \mathbf{C}_{\theta_2}$ for all $\theta_1 \leq \theta_2$). Unlike the Gumbel copula, which does not allow for negative dependence, Clayton and Frank copulas are able to model continuously the whole range of dependence between the lower Fréchet-Hoeffding copula, the product copula and the upper Fréchet-Hoeffding copula. Copulas with this property are called inclusive or comprehensive copulas. Frank copulas are the

only radially symmetric Archimedean copulas ($\mathbf{C} = \mathbf{C}^s$).

For Archimedean copulas, tail dependence and Kendall's tau coefficients can be expressed in terms of the generator function

$$\tau = 1 + 4 \int_0^1 \frac{\phi(u)}{\phi'(u)} du \tag{71}$$

$$\lambda_U = 2 - 2 \lim_{u \rightarrow 0} \frac{\phi^{-1}'(2u)}{\phi^{-1}'(u)} \tag{72}$$

$$\lambda_L = 2 \lim_{u \rightarrow \infty} \frac{\phi^{-1}'(2u)}{\phi^{-1}'(u)} \tag{73}$$

provided the derivatives and limits exist.

Archimedean copulas are interchangeable, which means that the dependence between any two (or more) random variables does not depend on which random variables we choose. In terms of credit risk analysis, this imposes an important restriction on the dependence structure since the default dependence introduced by an Archimedean copula is the same between any group of firms.

3. Marshall-Olkin Copula This copula was already mentioned when we dealt with joint defaults in intensity models. In its bivariate specification the Marshall-Olkin copula is given by

$$\begin{aligned} \mathbf{C}(u_1, u_2) &= \min \left\{ u_1^{1-\alpha_1} u_2, u_1 u_2^{1-\alpha_2} \right\} \\ &= u_1 u_2 \min \left\{ u_1^{-\alpha_1}, u_2^{-\alpha_2} \right\} \end{aligned} \tag{74}$$

for $\alpha_1, \alpha_2 \in (0, 1)$.⁴⁰

Copulas for Default Times

Within the reduced-form approach, we can distinguish two approaches to introduce default dependence using copulas. The first one, which we will refer to as Li's approach, was introduced by Li (1999) and represents one of the first attempts to use copula theory systematically in credit risk modeling. Li's approach takes as inputs the marginal default (survival) probabilities of each firm and derives the joint probabilities using a copula function.⁴¹ Although Li (1999) studies the case of a normal copula,

any other copula can be used within this framework.

If we are using a copula function as a joint distribution for default (survival) times, the simulated vector (u_1, \dots, u_I) of uniform $[0, 1]$ random variables from the copula will correspond to the default F_1, \dots, F_I (survival s_1, \dots, s_I) marginal distributions. Once we have simulated the vector (u_1, \dots, u_I) , we use it to derive the implied default times τ_1, \dots, τ_I such that $\tau_i = F_i^{-1}(u_i)$, or $\tau_i = s_i^{-1}(u_i)$ in the survival case, for $i = 1, \dots, I$.

The second approach was introduced by Schönbucher and Schubert (2001), and here we shall call it the Schönbucher-Schubert (SS) approach. In the algorithm to draw a default time in the case of a single firm, we simulated a realization u_i of a uniform $[0, 1]$ random variable U_i independent of $(\mathcal{G}_{X,t})$, and defined the time of default of firm i as τ_i such that

$$\exp\left(-\int_0^{\tau_i} \lambda_i(s) ds\right) = u_i \quad (75)$$

where λ_i is the default intensity process of firm i . The idea of the SS approach is to link the default thresholds U_1, \dots, U_I with a copula.

Schönbucher and Schubert consider that the processes $\lambda_1, \dots, \lambda_I$ are $(\mathcal{F}_{i,t})$ -adapted⁴² and call them pseudo default intensities. Thus, λ_i is the default intensity if investors only consider the information generated by the background filtration $(\mathcal{G}_{X,t})$ and by the default status of firm i , $(\mathcal{G}_{i,t})$. However, investors are not restricted to the information represented by $(\mathcal{F}_{i,t})$ as they also observe the default status of the rest of the firms. Therefore, λ_i is not the density of default with respect to all the information investors have available, as represented by (\mathcal{F}_t) , but rather with respect to a smaller information set.

To calculate the default (or survival) probabilities conditional to all the information that investors have available, (\mathcal{F}_t) , we cannot define those probabilities in terms of the pseudo default intensities $\lambda_1, \dots, \lambda_I$. We have to find the

“real” intensities implied by the investors’ information set. The difference between pseudo and real intensities lies in the fact that real intensities, in addition to all the information considered by pseudo intensities, include information about the default status of all firms. The default thresholds’ copula function includes this information in the SS approach.

In order to find the “real” default intensities h_1, \dots, h_I , which are (\mathcal{F}_t) -adapted, we need to combine both the pseudo default intensities and the copula function, which links the default thresholds. The pseudo default intensity λ_i includes information about the state variables and the default situation of firm i , and only coincides with the “real” default intensity h_i in cases of independent default or when the information of the market is restricted to $(\mathcal{F}_{i,t})$.⁴³

The simulation of the default times in this approach is exactly the same as in Li’s approach. The only difference with the SS approach is that it allows us to recover the dynamics of the “real” default intensities h_1, \dots, h_I , which include the default contagion effects implicit in the default threshold copula. In contrast to the models of Jarrow and Yu (2001) and Davis and Lo (1999), the SS approach allows the contagion effects to arise endogenously through the use of the copula.

Schönbucher (2003) calls the SS approach a dynamic approach in the sense that it considers the dynamics of the “real” default intensities h_1, \dots, h_I , as opposed to Li’s approach, which only considers the dynamics of the pseudo default intensities.

As Schönbucher and Schubert (2001) point out, this setup is very general, and the reader has freedom to choose the specification of the default intensities. We can introduce default correlation by both correlating the default intensities, for example with a CID model, and by using any of the copula approaches we have just presented.

In an extension of the SS approach, Rogge and Schönbucher (2003) propose not to use the normal or t -copulas but Archimedean copulas,

arguing that normal and t -copulas do not imply a realistic dynamic process for default intensities.

Galiani (2003) provides a detailed analysis of the use of copula functions to price multiname credit derivatives using both a normal and Student t copula.

Choosing and Calibrating the Copula

Once we have reviewed how to use copula theory in the context of joint default probabilities, we have to choose a copula and estimate its parameters. In order to choose a copula we should consider aspects such as the dependence structure each copula involves as well as the number of parameters we need to estimate.

Since the normal copula presents neither lower nor upper tail dependence, the use of multivariate normal distributions to model default (or price) behavior has been strongly criticized for not assigning enough probability to the occurrence of extreme events and, among them, the periods of default clustering. The use of the t -copula is the natural answer to the lack of tail dependence, since, subject to the degrees of freedom and covariance matrix, this copula exhibits tail dependence. The main problem in using a normal or t -copula is the number of parameters we have to estimate, which grows with the dimensionality of the copula.⁴⁴

Archimedean copulas are especially attractive because there exists a large number of one-parameter Archimedean copulas⁴⁵ which allows for a great variety of dependence structures. The disadvantage of Archimedean copulas is that they may impose too much dependence structure in the sense that, as they are interchangeable copulas, the dependence between any group of firms is the same independently of the firms we consider.

In case we decide to use an Archimedean copula, Genest and Rivest (1993) propose a procedure for identifying the Archimedean copula that best fits the data.⁴⁶ The problem is that they consider only the bivariate case and that,

as we shall see later, we need a sample of the marginal random variables (the random variables X_1, \dots, X_I whose marginal distributions we link to the copula function) that is available if we are modeling equity returns, but not if we are modeling default times. More generally, Fermanian and Scaillet (2004) discuss the issue of choosing the copula that best fits a given data set, using goodness-of-fit tests.

According to Durrleman, Nikeghbali, and Roncalli (2000):

There does not exist a systematic rigorous method for the choice of the copula: nothing can tell us that the selected family of copula will converge to the real structure dependence underlying the data. This can provide biased results since according to the dependence structure selected the obtained results might be different.

Jouanin et al. (2001) use the term model risk to denote this uncertainty in the choice of the copula.

Assuming we manage to select a copula function, we now face the estimation of its parameters. The main problem of the use of copula theory to model credit risk is the scarcity of default data from which to calibrate the copula.

We cannot rely on multiname credit derivatives, such as i^{th} -to-default products, to calibrate the copula because, in most cases, they are not publicly traded and also because of their lack of liquidity.

Imagine that, instead of fitting a copula to default times, we are fitting a copula to daily stock returns for I different firms. Let Y_1, \dots, Y_I be random variables denoting the daily returns of firms $i = 1, \dots, I$ with marginal distribution functions F_1, \dots, F_I and joint distribution function F . Sklar's theorem proves that there exists an I -dimensional copula C such that $F(y_1, \dots, y_I) = C(F_1(y_1), \dots, F_I(y_I))$ for all (y_1, \dots, y_I) in R^I . In this case, we have available, for each day, a sample of the random vector Y_1, \dots, Y_I that we can use to estimate the parameters of the copula. We would have to estimate the parameters of the marginal

distribution functions F_1, \dots, F_I and then estimate the parameters of the copula. Since, in our application to default times, we already have the marginal distributions, determined by the specification of the marginal default intensities, we are left with the estimation of the copula parameters. Providing we have a large sample of the random variables Y_1, \dots, Y_I , we can estimate the copula parameters in several ways.⁴⁷

If the copula is differentiable we can always use maximum likelihood to estimate the parameters.⁴⁸ De Matteis (2001) mentions that this parametric method may be convenient when we work with a large data set, but in case there are outliers or if the marginal distributions are heavy tailed, a nonparametric approach may be more suitable.

A nonparametric approach would involve the use of the sample version of a dependence measure, such as Kendall's tau or Spearman's rho (or both),⁴⁹ to calibrate the copula parameters. However, this nonparametric approach is restricted to the bivariate case, and we would need to have at least the same sample dependence measures as copula parameters.⁵⁰

The estimation methods exposed above rely on the availability of a large sample of the random variables Y_1, \dots, Y_I . However, this is not the case when we work with default times. We do not have available a large sample of default times for the I firms. In fact, we do not have a single realization of the default times random vector.

One solution is to assume that the marginal default (survival) probabilities and the marginal distributions of the equity returns share the same copula, that is, share the same dependence structure, and use equity returns to estimate the copula parameters. But this shortcut has its own drawbacks. We need to fit a copula to a set of given marginal distributions for the default (survival) times, which are characterized by a default intensity for each firm. Ideally we should estimate the parameters of the copula function using default times data. However, we rarely have enough default times data

available such as to properly estimate the parameters of the copula function. In those cases, we must rely on other data sources to calibrate the copula function. For example, a usual practice is to calibrate the copula using equity data of the different firms. However, the dependence of the firms' default probabilities will probably differ from the dependence in the evolution of their equity prices.

Another way of dealing with the estimation of the copula parameters is, as Jouanin et al. (2001) propose, through the use of "original methods that are based on the practice of the credit market rather than mimicking statistical methods that are never used by practitioners." They suggest a method based on Moody's diversity score.⁵¹ The diversity score or binomial expansion technique consists of transforming a portfolio of (credit dependent) defaultable bonds on an equivalent portfolio of uncorrelated and homogeneous credits assumed to mimic the default behavior of the original portfolio, using the so-called diversity score parameter, which depends on the degree of diversification of the original portfolio. We then match the first two moments of the number of defaults within a fixed time horizon for both the original and the transformed portfolio. Since the original portfolio assumes default dependence, the distribution of the number of defaults will depend on the copula parameters. In the transformed portfolio, that is, independent defaults, the number of defaults follows a binomial distribution with some probability p . Matching the first two moments of the number of defaults in both portfolios, we would extract an estimation for the probability p and for the copula parameters.⁵² However, Moody's diversity score approach has its own drawbacks. Among others, it is a static model with a fixed time horizon, that is, it does not consider when defaults take place but only the number of defaults within the fixed time horizon. In fact, the Committee on the Global Financial System (Bank for International Settlements) suggests, in its last report,⁵³ that diversity scores "are a fairly crude measure of

the degree of diversification in a portfolio of credits.”

Similarly to the choice of the copula function, there does not exist a rigorous method to estimate the parameters of the copula. We can talk about parameter risk which, together with the model risk mentioned earlier, are the principal problems we face if we use the copula approach in the modeling of dependent defaults.

KEY POINTS

- There are two primary types of models in the literature that attempt to describe default processes: structural and reduced-form models. Intensity models represent the most extended type of reduced-form models. In contrast to structural models, the time of default in intensity models is not determined via the value of the firm, but it is the first jump of an exogenously given jump process. The fundamental idea of the intensity-based framework is to model the default time as the first jump of a Poisson process. The default intensity of the Poisson process, also referred to as the hazard rate, can be deterministic (constant or time dependent) or stochastic.
- We review three different ways of introducing default correlations among firms in the framework of intensity models: the conditionally independent defaults (CID) approach, contagion models, and copula functions.
- CID models generate credit risk dependence among firms through the dependence of the firms' intensity processes on a common set of state variables. Firms' default rates are independent once we fix the realization of the state variables. Different CID models differ in their choices of the state variables and the processes they follow. Extensions of CID models introduce joint jumps in the firms' default processes or common default events.
- Contagion models extend the CID approach to account for the empirical observation of de-

fault clustering (periods in which firms' credit risk increases simultaneously and in which the majority of defaults take place). They are based on the idea that, when a firm defaults, the default intensities of related firms jump (upwards), that is, the default of one firm increases the default probabilities of other firms (to the point of potentially causing the default of some of them). These models include, on the specification of default intensities, the existence of contagion sources among firms, which can be explained by either their commercial/financial relationships or simply by their common exposure to the economy.

- In CID and contagion models the specification of the individual intensities includes all the default dependence structure between firms. In contrast, the copula approach separates individual default probabilities from the credit risk dependence structure.
- A copula is a function that links univariate marginal distributions to the joint multivariate distribution function. The copula approach takes as given the marginal default probabilities of the different firms and plugs them into a copula function, which provides the model with the dependence structure to generate joint default probabilities. This approach separates the modeling and estimation of the individual default probabilities, determined by the default intensity processes, from the modeling and calibration or estimation of the device that introduces the credit risk dependence, the copula.

NOTES

1. Brody, Hughston, and Macrina (2007) present an alternative reduced-form model based on the amount and precision of the information received by market participants about the firm's credit risk. Such a model does not require the use of default intensities; it belongs to the reduced-form approach because (like intensity models) it relies on market prices of defaultable

instruments as the only source of information about the firms' credit risk.

2. An event is a subset of Ω , namely a collection of possible outcomes. σ -algebras are models for information, and filtrations models for flows of information.
3. For some applications we may wish to enlarge this category of probability measures by relaxing the martingale condition to a local martingale condition, though this point does not concern us in what follows.
4. Given the filtered probability space Π , an (\mathcal{F}_t) -adapted process X_t is a Markov process with respect to (\mathcal{F}_t) if

$$E[f(X_t) | \mathcal{F}_s] = E[f(X_t) | X_s]$$

with probability one, for all $0 \leq s \leq t$, and for every bounded function f . This means that the conditional distribution at time s of X_t , given all available information, depends only on the current state X_s .

5. For a more detailed exposition see Lando (1994) and Chapter 5 in Schönbucher (2003).
6. This specification of the recovery rate incorporates all possible ways of dealing with recovery payments considered in the literature. Here we consider a continuous version of the recovery rate, that is, R_t is measured and received precisely at the default time. In the discrete version of the recovery rate, R_t is measured and received on the first date after default among a prespecified list $T_1 < \dots < T_n$ of times, where T_n is the maturity date T .
7. See Hughston and Turnbull (2001).
8. See proof on Lando (1994, Proposition 3.1) and Bielecki and Rutkowski (2002, Proposition 8.2).
9. For an extensive review of the treatment of recovery rates see Chapter 6 in Schönbucher (2003).
10. Houweling and Vorst (2001) consider the RFV specification for pricing credit default swaps.

11. See Duffie and Singleton (1999a) and Jarrow (1999).
12. There exist some empirical works that, under some specifications of λ_t and r_t , find that the value of the recovery rate does not substantially affect the results, as long as the recovery rate lies within a logical interval. See, for instance, Houweling and Vorst (2001) and Elizalde (2005a).
13. See Houweling and Vorst (2001) and Elizalde (2005a) for a comparison of different specifications of (deterministic) time-dependent intensity rates.
14. For a detailed description of affine processes see Duffie and Kan (1996), Duffie (1998), Duffie, Pan, and Singleton (2000), Duffie, Filipovic, and Schachermayer (2002), and Appendix A in Duffie and Singleton (2003). An affine jump-diffusion process is a jump-diffusion process for which the drift vector, instantaneous covariance matrix, and jump intensities all have affine dependence on the state vector. If X_t is a Markov process in some space state $D \subset \mathcal{R}^d$, X_t is an affine jump-diffusion if it can be expressed as

$$dX_t = \mu(X_t)dt + \sigma(X_t)dW_t + dq_t$$

where W_t is an (\mathcal{F}_t) -Brownian motion in \mathcal{R}^d , $\mu: D \rightarrow \mathcal{R}^d$, $\sigma: D \rightarrow \mathcal{R}^d$ and q is a pure jump process whose jumps have a fixed probability distribution ν on \mathcal{R}^d and arrive with intensity $\{\psi(X_t): t \geq 0\}$, for some constant $\psi: D \rightarrow [0, \infty)$. That is, the drift vector μ , instantaneous covariance matrix $\sigma\sigma'$ and jump intensities ψ all have affine dependence on the state vector X_t . Intuitively this means that, conditional on the path of X_t , the jump times of q are the jump times of a Poisson process with time varying-intensity $\{\psi(X_t): t \geq 0\}$, and that the size of the jump at time T is independent of $\{X_s: 0 \leq s \leq t\}$ and has the probability distribution ν .

15. See Duffie and Kan (1996) and Duffie, Pan, and Singleton (2000).

16. For the basic affine model, the coefficients can be calculated explicitly. See Duffie and Garleanu (2001), Appendix A in Duffie and Singleton (2003), and Duffie, Pan, and Singleton (2000) for details and extensions.
17. Duffie, Pan, and Singleton (2000) developed a similar closed-form expression to the second term of the price of a defaultable zero-coupon bond $Q(t, T)$

$$E \left[\int_t^T R_s \lambda_s \exp \left(- \int_t^s (r_u + \lambda_u) du \right) ds \mid \mathcal{F}_t \right]$$

Using their expression, the pricing of defaultable zero-coupon bonds with constant recovery of face value reduces to the computation of a one-dimensional integral of a known function.

18. Several versions of the modeling of r_t and λ_t in this framework can be found in Duffie, Schroder, and Skidas (1996), Duffee (1999), Duffie and Singleton (1999, 2003), Kijima (2000), Kijima and Muromachi (2000), Duffie and Garleanu (2001), Bielecki and Rutkowski (2002), and Schönbucher (2003). For the estimation of an affine process intensity model without jumps see Duffee (1998) and Duffie, Pedersen, and Singleton (2003).
19. If Y is an n -dimensional random vector and, for some $\mu \in R^n$ and some $n \times n$ nonnegative definite, symmetric matrix Σ , the characteristic function $\psi_{Y-\mu}(t)$ of $Y - \mu$ is a function of the quadratic form $t^T \Sigma t$, $\psi_{Y-\mu}(t) = \phi(t^T \Sigma t)$. We say that Y has an elliptical distribution with parameters μ , Σ and ϕ . For example, normal and Student t distributions are elliptical distributions. For a more detailed treatment of elliptical distributions see Bingham and Kiesel (2002) and references cited therein.
20. See Embrechts, McNeal, and Straumann (1999) and Embrechts, Lindskog, and McNeil (2001).
21. We can always consider a model such as

$$d\lambda_{i,t} = \kappa_i (\theta_i - \lambda_{i,t}) dt + \sigma_i \sqrt{\lambda_{i,t}} dW_{i,t} + dq_{i,t}$$

- for each firm i , and introduce correlation via the Brownian motions $W_{1,t}, \dots, W_{I,t}$.
22. Duffee (1999), Driessen (2005), and Elizalde (2005b) use latent variables instead of state variables. Collin-Dufresne, Goldstein, and Martin (2001) show that financial and economic variables cannot explain the correlation structure of intensity processes. Latent factors are modeled as affine diffusions and estimated through a maximum likelihood procedure based on the Kalman filter.
 23. While Driessen (2005) considers that all firms with the same rating are affected in the same way by common factors, Elizalde (2005b) allows for the effect of each common factor to differ across firms, which increases the flexibility of the credit risk correlation structure.
 24. See also Kijima (2000), Kijima and Muromachi (2000), and Giesecke (2002b).
 25. This is a basic affine process with parameters $(\kappa_i, \theta_i, \sigma_i = 0, \mu, \gamma_i)$.
 26. See Embrechts, Lindskog, and McNeil (2001) and Giesecke (2002b).
 27. Extending the diversity score (or binomial expansion technique) of Moody's.
 28. This dynamic version is introduced in Davis and Lo (2001).
 29. See Yu (2002a) and Frey and Backhaus (2003) for an extension of the Jarrow and Yu (2001) model.
 30. See Sklar (1959) and Frees and Valdez (1998).
 31. Note that $F_i(t_i) = F(\infty, \dots, t_i, \dots, \infty)$ and $s_i(t_i) = s(0, \dots, t_i, \dots, 0)$.
 32. For a more detailed description of copula theory see Joe (1997), Frees and Valdez (1998), Nelsen (1999), Costinot, Roncalli, and Teiletche (2000), Embrechts, Lindskog, and McNeil (2001), De Matteis (2001), and Georges et al. (2001).
 33. A more formal definition would be the following (Frey, McNeil, and Nyfeler 2001): An I -dimensional copula \mathbf{C} is a function $\mathbf{C} : [0, 1]^I \rightarrow [0, 1]$ with the following properties:

- Grounded: For all $u \in [0, 1]^I$, $\mathbf{C}(u) = 0$ if at least one coordinate $u_j = 0$, $j = 1, \dots, I$.
- Reflective: If all coordinates of u are 1 except u_j then $\mathbf{C}(u) = u_j$, $j = 1, \dots, I$.
- I -increasing: The \mathbf{C} -volume of all hypercubes with vertices in $[0, 1]^I$ is positive, *i.e.*

$$\sum_{i_1=1}^2 \dots \sum_{i_I=1}^2 (-1)^{i_1+\dots+i_I} \mathbf{C}(u_{1,i_1}, \dots, u_{I,i_I}) \geq 0$$

for all $(u_{1,1}, \dots, u_{I,1})$ and $(u_{1,2}, \dots, u_{I,2})$ in $[0, 1]^I$ with $u_{j,1} \leq u_{j,2}$ for all $j = 1, \dots, I$.

34. We will use \mathbf{C}^d , or simply \mathbf{C} , to denote the copula function of default times and \mathbf{C}^s for the copula function of survival times.
35. See Georges et al. (2001) for a complete characterization of the relation between default and survival copulas.
36. \mathbf{C}^- is always a copula, but \mathbf{C}^+ is only a copula for $I \geq 3$.
37. A simple interpretation of Spearman's rho is the following. Let (Y_1, Y_2) be a random vector of continuous random variables with the same joint distribution function H (whose margins are F_1 and F_2) and copula C , and consider the random variables $U = F(Y_1)$ and $V = F(Y_2)$. Then, we can write the Spearman's rho coefficient of (Y_1, Y_2) as

$$\begin{aligned} \rho_S(Y_1, Y_2) &= 12 \iint_{[0,1]^2} \mathbf{C}(u, v) \, dudv - 3 \\ &= 12\mathbf{E}[UV] - 3 = \frac{\mathbf{E}[UV] - \frac{1}{4}}{\frac{1}{12}} = \\ &= \frac{\text{Cov}(U, V)}{\sqrt{\text{Var}(U)\text{Var}(V)}} = \rho(U, V) \\ &= \rho(F_1(Y_1), F_2(Y_2)) \end{aligned}$$

where ρ denotes the Pearson or linear correlation coefficient. So the Spearman's rho of the vector (Y_1, Y_2) is the Pearson correlation of the random variables $F_1(Y_1)$ and $F_2(Y_2)$.

38. Since $\mathbf{P}[Y_1 > F_1^{-1}(u) \mid Y_2 > F_2^{-1}(u)]$ can be written as

$$\frac{1 - \mathbf{P}[Y_1 \leq F_1^{-1}(u)] - \mathbf{P}[Y_2 \leq F_2^{-1}(u)] + \mathbf{P}[Y_1 \leq F_1^{-1}(u), Y_2 \leq F_2^{-1}(u)]}{1 - \mathbf{P}[Y_2 \leq F_2^{-1}(u)]}$$

we can express λ_U as

$$\lambda_U = \lim_{u \nearrow 1} \frac{1 + \mathbf{C}(u, u) - 2u}{1 - u}$$

39. See Embrechts, Lindskog, and McNeil (2001) and Nelsen (1999) for a more detailed description.
40. For a multivariate version of the Marshall-Olkin copula, see Embrechts, Lindskog, and McNeil (2001).
41. Li (1999) considers a copula that links individual survival probabilities to model the joint survival probability. However, as we have explained previously, this can be done exactly in the same way if we consider default probabilities instead of survival probabilities.
42. Remember that $(\mathcal{F}_{i,t}) = (\mathcal{G}_{X,t}) \vee (\mathcal{G}_{i,t})$ is the information generated by the state variables plus the information generated by the default status of firm i .
43. This distinction between pseudo and real default intensities can also be found in Gregory and Laurent (2002).
44. If we are considering I firms, the number of parameters of the normal copula will be $\frac{I(I-1)}{2}$, and we have to add the degrees of freedom parameter in the case of the t -copula.
45. See Nelsen (1999).
46. See also De Matteis (2001) and Frees and Valdez (1998).
47. For a more detailed description of copula parameters estimation see Frees and Valdez (1998), Bouy e et al. (2000), Durrleman, Nikeghbali, and Roncalli (2000), De Matteis (2001), and Patton (2002).
48. We have to distinguish the case in which we estimate the parameters of the marginal distributions and the copula function altogether from the case in which we first estimate the parameters of the marginal distributions and then, using those parameters, we estimate the parameters of the copula function. The latter approach is

called inference functions for margins or the IFM method.

49. Imagine we have N random samples of a bivariate vector (Y_1, Y_2) , let us denote them by (y_1^n, y_2^n) , $n = 1, \dots, N$. The sample estimators of Kendall's tau ($\hat{\tau}$) and Spearman's rho ($\hat{\rho}_s$) are given by:

$$\hat{\rho}_s = \frac{12}{N(N^2 - 1)} \sum_{n=1}^N \left(\text{rank}(y_1^n) - \frac{n(n+1)}{2} \right) \times \left(\text{rank}(y_2^n) - \frac{n(n+1)}{2} \right)$$

$$\hat{\tau} = \frac{c - d}{c + d} = \frac{2}{N(N-1)} \sum_{n < m} \text{sign}[(y_1^n - y_1^m)(y_2^n - y_2^m)]$$

where c and d are the number of concordant and discordant pairs, respectively.

50. In some cases analytical expressions for the dependence measures are available. Otherwise we have to use a root-finding procedure.
51. For a detailed description of the diversity score method see Cifuentes, Murphy, and O'Connor (1996), Cifuentes and O'Connor (1996), and Cifuentes and Wilcox (1998).
52. See Jouanin et al. (2001).

Structural Models in Credit Risk Modeling

ABEL ELIZALDE, PhD

Credit Derivatives Strategy, J.P. Morgan

Abstract: Structural models and reduced-form models are the two primary types of credit risk models that seek to statistically describe default processes. Structural models use the evolution of firms' structural variables, such as asset and debt values, to model the time of default. In contrast, reduced-form models do not consider structural variables in an explicit manner when modeling default processes; instead, they model default as an exogenously driven process. Structural models include first passage models, liquidity process models, and state dependent models.

In this entry we review the structural approach for credit risk modeling, both considering the case of a single firm and the case with default dependencies between firms. In the single firm case, we review the *Merton (1974) model* and first passage models, examining their main characteristics and extensions. Liquidation process models extend first passage models to account for the possibility of a lengthy liquidation process, which might or might not end up in default. Finally, we review *structural models* with state-dependent cash flows (recession vs. expansion) or debt coupons (rating-based). The estimation of structural models is also addressed in this entry, covering the different ways proposed in the literature. Finally, we present some approaches to model default dependencies between firms within the structural approach. These approaches account for two types of *default correlations*: cyclical default correlation and contagion effects.

REVIEW OF STRUCTURAL MODELS

Structural models use the evolution of firms' structural variables, such as asset and debt values, to determine the time of default. Merton's model (1974) was the first modern model of default and is considered the first structural model. In Merton's model, a firm defaults if, at the time of servicing the debt, its assets are below its outstanding debt. A second approach, within the structural framework, was introduced by Black and Cox (1976). In this approach defaults occur as soon as the firm's asset value falls below a certain threshold. In contrast to the Merton approach, default can occur at any time.

Reduced form models do not consider the relation between default and firm value in an explicit manner. In contrast to structural models, the time of default in intensity models is not

determined via the value of the firm, but it is the first jump of an exogenously given jump process. The parameters governing the default hazard rate are inferred from market data.¹

Structural default models provide a link between the credit quality of a firm and the firm's economic and financial conditions. Thus, defaults are endogenously generated within the model instead of exogenously given as in the reduced approach. Another difference between the two approaches refers to the treatment of recovery rates: Whereas reduced models exogenously specify recovery rates, in structural models the value of the firm's assets and liabilities at default will determine recovery rates.

The structural literature on credit risk starts with the paper by Merton (1974), who applies the option pricing theory developed by Black and Scholes (1973) to the modeling of a firm's debt. In Merton's model, the firm's capital structure is assumed to be composed by equity and a zero-coupon bond with maturity T and face value of D . The firm's equity is simply a European call option with maturity T and strike price D on the asset value and, therefore, the firm's debt value is just the asset value minus the equity value. This approach assumes a very simple and unrealistic capital structure and implies that default can only happen at the maturity of the zero-coupon bond.

Black and Cox (1976) introduced the first of the so-called *first passage models* (FPM). First passage models specify default as the first time the firm's asset value hits a lower barrier, allowing default to take place at any time. When the default barrier is exogenously fixed, as in Black and Cox (1976) and Longstaff and Schwartz (1995), it acts as a safety covenant to protect bondholders. Alternatively it can be endogenously fixed as a result of the stockholders' attempt to choose the default threshold that maximizes the value of the firm.²

Structural models have considered interest rates both as nonstochastic processes³ and as stochastic processes.^{4,5}

In first passage models, by definition, default occurs the first time the asset value goes below a certain lower threshold, that is, the firm is liquidated immediately after the default event. In contrast with first passage models, a new set of models has been put forward, supported by recent theoretical and empirical research, where a default event does not immediately cause liquidation but it represents the beginning of a process, the liquidation process, which might or might not cause liquidation after it is completed. This practice is consistent, for example, with Chapter 11 of the U.S. Bankruptcy Law, where firms filing for bankruptcy are granted a court-supervised grace period (up to several years) aimed at sorting out their financial problems in order to, if possible, avoid liquidation. We label those models *liquidation process models* (LPM).

State dependent models (SDM) represent, together with LPM, two recent efforts to incorporate into structural models different real-life phenomena. Although theoretically they make good sense, they lack empirical research testing their performance. SDM assume that some of the parameters governing the firm's ability to generate cash flows or its funding costs are state dependent, where states can represent the business cycle (recession vs. expansion) or the firm's external rating.

After the single firm case, we review some structural models for default correlations, in order to account for both cyclical default correlation⁶ as well as credit risk contagion effects.⁷ We will finish the default correlation section mentioning the so-called factor models.⁸

We concentrate on the review of the dynamics of the processes that generate the default times, without paying attention to the valuation formulas for defaultable bonds that each model generates. The aim of this entry is to serve as an introduction and guide to the literature of structural credit risk models. We provide an extensive list of references for each model specification and possible extensions or related papers.

SINGLE FIRM

We denote the physical and risk-neutral probability measures as $\bar{\mathbf{P}}$ and \mathbf{P} respectively, and assume an arbitrage-free market.⁹ Unless otherwise stated, all probabilities and expectations are taken under the risk-neutral measure. The model for the default-free term structure of interest rates is given by a short-rate process r_t .

Merton's Model

Merton (1974) makes use of the Black and Scholes (1973) option pricing model to value corporate liabilities. This is a straightforward application only if we adapt the firm's capital structure and the default assumptions to the requirements of the Black-Scholes model. Let us assume that the capital structure of the firm is comprised by equity and by a zero-coupon bond with maturity T and face value of D , whose values at time t are denoted by E_t and $z(t, T)$ respectively, for $0 \leq t \leq T$. The firm's asset value V_t is simply the sum of equity and debt values. Under these assumptions, equity represents a call option on the firm's assets with maturity T and strike price of D . If at maturity T the firm's asset value V_T is enough to pay back the face value of the debt D , the firm does not default and shareholders receive $V_T - D$. Otherwise ($V_T < D$) the firm defaults, bondholders take control of the firm, and shareholders receive nothing. Implicit in this argument is the fact that the firm can only default at time T . This assumption is important to be able to treat the firm's equity as a vanilla European call option, and therefore apply the Black-Scholes pricing formula.

The rest of the assumptions Merton (1974) adopts are the inexistence of transaction costs, bankruptcy costs, taxes, or problems with indivisibilities of assets; continuous time trading; unrestricted borrowing and lending at a constant interest rate r ; no restrictions on the short selling of the assets; the value of the firm is invariant under changes in its capital structure

(Modigliani-Miller theorem), and that the firm's asset value follows a diffusion process.

The firm's asset value is assumed to follow a diffusion process given by

$$dV_t = rV_t dt + \sigma_V V_t dW_t \quad (1)$$

where σ_V is the (relative) asset volatility and W_t is a Brownian motion.¹⁰

The payoffs to equityholders and bondholders at time T under the assumptions of this model are respectively, $\max\{V_T - D, 0\}$ and $V_T - E_T$, that is,

$$E_T = \max\{V_T - D, 0\} \quad (2)$$

$$z(T, T) = V_T - E_T \quad (3)$$

Applying the Black-Scholes pricing formula, the value of equity at time t ($0 \leq t \leq T$) is given by

$$\begin{aligned} E_t(V_t, \sigma_V, T - t) \\ = e^{-r(T-t)} \left[e^{r(T-t)} V_t \Phi(d_1) - D \Phi(d_2) \right] \end{aligned} \quad (4)$$

where $\Phi(\cdot)$ is the distribution function of a standard normal random variable and d_1 and d_2 are given by

$$d_1 = \frac{\ln\left(\frac{e^{r(T-t)} V_t}{D}\right) + \frac{1}{2} \sigma_V^2 (T - t)}{\sigma_V \sqrt{T - t}} \quad (5)$$

$$d_2 = d_1 - \sigma_V \sqrt{T - t} \quad (6)$$

The probability of default at time T is given by

$$P[V_T < D] = \Phi(-d_2) \quad (7)$$

Therefore, the value of the debt at time t is $z(t, T) = V_t - E_t$.

In order to implement Merton's model we have to estimate the firm's asset value V_t , its volatility σ_V (both unobservable processes), and we have to transform the debt structure of the firm into a zero-coupon bond with maturity T and face value D .

The maturity T of the zero-coupon bond can be chosen either to represent the maturity structure of the debt, for example as the Macaulay duration of all the liabilities, or simply as a required time horizon (for example, in case we

are pricing a credit derivative with some specific maturity).

Criticisms and Extensions

The main advantage of Merton's model is that it allows us to directly apply the theory of European options pricing developed by Black and Scholes (1973). But to do so the model needs to make the necessary assumptions to adapt the dynamics of the firm's asset value process, interest rates, and capital structure to the requirements of the Black-Scholes model. There is a trade-off between realistic assumptions and ease of implementation, and Merton's model opts for the latter one. All extensions to this model introduce more realistic assumptions trying to end up with a model not too difficult to implement and with closed, or at least numerically feasible, solutions for the expressions of the debt value and the default probabilities. Merton (1974) presents some extensions to the model, in order to account for coupon bonds, callable bonds, stochastic interest rates, and relaxing the assumption that the Modigliani-Miller theorem holds.

One problem of Merton's model is the restriction of default time to the maturity of the debt, ruling out the possibility of an early default, no matter what happens with the firm's value before the maturity of the debt. If the firm's value falls down to minimal levels before the maturity of the debt but it is able to recover and meet the debt's payment at maturity, the default would be avoided in Merton's approach.

Another handicap of the model is that the usual capital structure of a firm is much more complicated than a simple zero-coupon bond. Geske (1977, 1979) considers the debt structure of the firm as a coupon bond, in which each coupon payment is viewed as a compound option and a possible cause of default. At each coupon payment, the shareholders have the option either to make the payment to bondholders,¹¹ obtaining the right to control the firm until the next coupon, or to not make the payment, in which case the firm defaults. Geske also extends the model to consider character-

istics such as sinking funds, safety covenants, debt subordination, and payout restrictions.

The assumption of a constant and flat term structure of interest rates is another major criticism the model has received. Jones et al. (1984, p. 624) suggest that "there exists evidence that introducing stochastic interest rates, as well as taxes, would improve the model's performance." Stochastic interest rates allow us to introduce correlation between the firm's asset value and the short rate, and have been considered, among others, by Ronn and Verma (1986), Kim, Ramaswamy, and Sundaresan (1993), Nielsen et al. (1993), Longstaff and Schwartz (1995), Briys and de Varenne (1997), and Hsu, Saá-Requejo, and Santa-Clara (2004).

Another characteristic of Merton's model, which will also be present in some of the FPM, is the predictability of default. Since the firm's asset value is modeled as a geometric Brownian motion and default can only happen at the maturity of the debt, it can be predicted with increasing precision as the maturity of the debt comes near. As a result, in this approach default does not come as a surprise, which makes the models generate very low short-term credit spreads.¹² As we shall review, introducing jumps in the process followed by the asset value has been one of the solutions considered to this problem.

Delianedis and Geske (2001) study the proportion of the credit spread that, in a corporate bond data set, is explained by default risk, using the Merton (1974) and Geske (1977) frameworks. They conclude that it only explains a small fraction of the credit spreads; the rest is attributable to taxes, jumps, liquidity, and market risk factors. They also include a jump component in the Merton model finding that (p. 24) "while jumps may explain a portion of the residual spread it is unlikely that jumps can explain it entirely."

First Passage Models

First passage models were introduced by Black and Cox (1976) extending the Merton model to

the case when the firm may default at any time, not only at the maturity date of the debt.

Consider, as in the previous section, that the dynamics of the firm's asset value under the risk-neutral probability measure \mathbf{P} are given by the diffusion process

$$dV_t = rV_t dt + \sigma_V V_t dW_t \quad (8)$$

and that there exists a lower level of the asset value such that the firm defaults once it reaches this level. Although Black and Cox (1976) considered a time-dependent default threshold, let us assume first a constant default threshold $K > 0$. If we are at time $t \geq 0$, default has not been triggered yet and $V_t > K$, then the time of default τ is given by

$$\tau = \inf \{s \geq t \mid V_s \leq K\} \quad (9)$$

Using the properties of the Brownian motion W_t , in particular the reflection principle, we can infer the default probability from time t to time T :¹³

$$P[\tau \leq T \mid \tau > t] = \Phi(h_1) + \exp\left\{2\left(r - \frac{\sigma_V^2}{2}\right) \ln\left(\frac{K}{V_t}\right) \frac{1}{\sigma_V^2}\right\} \Phi(h_2) \quad (10)$$

where

$$h_1 = \frac{\ln\left(\frac{K}{e^{r(T-t)}V_t}\right) + \frac{\sigma_V^2}{2}(T-t)}{\sigma_V\sqrt{T-t}} \quad (11)$$

$$h_2 = h_1 - \sigma_V\sqrt{T-t} \quad (12)$$

FPM have been extended to account for stochastic interest rates, bankruptcy costs, taxes, debt subordination, strategic default, time-dependent and stochastic default barriers, jumps in the asset value process, and so on. Although these extensions introduce more realism into the model, they increment its analytical complexity.¹⁴

The default threshold, always positive, can be interpreted in various ways. We can think of it as a safety covenant of the firm's debt, which allows the bondholders to take control of the company once its asset value has reached this level. The safety covenant would

act as a protection mechanism for the bondholders against an unsatisfactory corporate performance. In this case, the default threshold would be deterministic, although possibly time dependent, and exogenously fixed when the firm's debt is issued. Kim, Ramaswamy, and Sundaresan (1993) and Longstaff and Schwartz (1995) assume an exogenously given constant default threshold K . Black and Cox (1976) consider a time-dependent default barrier given by $e^{-\gamma(T-t)}K$. A particular case of the Black and Cox default threshold specification is to consider $\gamma = r$, that is, to consider a default barrier equal to the face value of the debt discounted at the risk-free interest rate. In that case, the default threshold can be made stochastic if the model considers a stochastic process for the interest rate, as in Briys and de Varenne (1997).

Longstaff and Schwartz (1995) choose a constant default threshold and point out that "since it is the ratio of V_t to K , rather than the actual value of K , that plays the major role in our analysis, allowing a more general specification for K simply makes the model more complex without providing additional insight into the valuation of risky debt."

Hsu, Saá-Requejo, and Santa-Clara (2004) suggest that V_t and K do not matter directly to the valuation of default risky bonds but only through their ratio, which is a measure of the solvency of the firm. They model the default threshold as a stochastic process, which together with the stochastic process assumed for the firm's asset value, allow them to obtain the stochastic process of the ratio $\frac{V_t}{K}$. The dynamics of the ratio $\frac{V_t}{K}$ are used to price corporate bonds.

The default threshold can also be chosen endogenously by the stockholders to maximize the value of the equity.¹⁵ The literature has also considered the possibility of negotiation processes between stockholders and bondholders when the firm goes near the point of financial distress, from which the default threshold is determined.¹⁶

Similar to the description of the choice of the face-value of the zero-coupon in the Merton model, in FPM the default threshold can be

calculated as a weighted average of short and long-term debts.

Interest rates can be considered either as a constant or as a stochastic process.¹⁷ The stochasticity of interest rates allows the model to introduce correlation between asset value and interest rates, and to make the default threshold stochastic, in the cases when it is specified as the discounted value of the face value of the debt. Nielsen et al. (1993) and Longstaff and Schwartz (1995) consider a Vasicek process for the interest rate, correlated with the firm's asset value:

$$dV_t = (c - d)V_t dt + \sigma_V V_t dW_t \quad (13)$$

$$dr_t = (a - br_t) dt + \sigma_r d\bar{W}_t \quad (14)$$

$$d\bar{W}_t dW_t = \rho dt \quad (15)$$

where \bar{W}_t and W_t are correlated Brownian motions. Other specifications for the stochastic process of the short rate have been considered. For example Kim, Ramaswamy, and Sundaresan (1993) suggest a CIR process

$$dr_t = (a - br_t) dt + \sigma_r \sqrt{r_t} d\bar{W}_t \quad (16)$$

and Briys and de Varenne (1997) a generalized Vasicek process

$$dr_t = (a(t) - b(t)r_t) dt + \sigma_r(t) d\bar{W}_t \quad (17)$$

Hsu, Saá-Requejo, and Santa-Clara (2004) consider both the case of independence between risk-free interest rates and the default generating mechanism (given by the dynamics of the ratio $\frac{V_t}{K}$) and the case of correlation between both processes, specifying the risk-free rate as a CIR process. They present an interesting empirical illustration of the model, covering the calibration of the risk-free rate process and the estimation of the model's parameter through the generalized method of moments.

Drawbacks and Extensions

The principal drawback of FPM is the analytical complexity that they introduce, which is increased if we consider stochastic interest rates or endogenous default thresholds. This mathe-

matical complexity makes it difficult to obtain closed form expressions for the value of the firm's equity and debt, or even for the default probability, forcing us to make use of numerical procedures.

The empirical testing of FPM and structural models in general has not been very successful.¹⁸ Eom, Helwege, and Huang (2003), who carry out an empirical analysis of five models (Merton, Geske, Leland and Toft, Longstaff and Schwartz, and Collin-Dufresne and Goldstein), conclude that (p. 502)

Using estimates from the implementations we consider most realistic, we agree that the five structural bond pricing models do not accurately price corporate bonds. However, the difficulties are not limited to the underprediction of spreads. . . . they all share the same problem of inaccuracy, as each has a dramatic dispersion of predicted spreads.

Zhou (1997, Abstract) indicates that "the empirical application of a diffusion approach has yielded very disappointing results."

Another drawback of the structural models presented before is the so-called predictability of defaults. Generally, structural models consider continuous diffusion processes for the firm's asset value and complete information about the asset value and default threshold. In this setting, the actual distance from the asset value to the default threshold tells us the nearness of default, in such a way that if we are far away from default the probability of default in the short-term is close to zero, because the asset value process needs time to reach the default point. The knowledge of the distance of default and the fact that the asset value follows a continuous diffusion process makes default a predictable event, that is, default does not come as a surprise.

This predictability of defaults makes the models generate short-term credit spreads close to zero. In contrast, it is observed in the market that even short-term credit spreads are bounded from below, incorporating the possibility of an unexpected default or deterioration in the firm's credit quality.¹⁹

The same characteristics of the structural models that imply the predictability of default also imply predictability of recovery. In models that do not consider strategic defaults, the bondholders get the remaining value of the firm in case of default, which is precisely the value of the default threshold at default. Thus, if we assume complete information about the asset value and default threshold, the recovery rate is also a predictable quantity.

Essentially, two ways out of the predictability effects of structural models have been proposed in the literature. The predictability of default comes from the assumption of investors' perfect knowledge of the firm's asset value and default threshold. In practice, it is not possible to deduce from the capital structure of the firm neither the value of the firm V_t , its volatility σ_V , nor the level of the default threshold. If we consider incomplete information about either the firm value process, the default threshold (or both), investors can only infer a distribution function for these processes, which makes defaults impossible to predict. These considerations can be found, among others, in Duffie and Lando (2001), Giesecke (2005), and Jarrow and Protter (2004).²⁰

The second way consists in incorporating jumps in the dynamics of the firm value, which implies that the asset value of the firm can suddenly drop, reducing drastically the distance of default (between the asset value and default threshold), or even causing a default if the drop is sufficiently high. Thus, default is not a predictable event anymore, the default probabilities for short maturities do not tend to zero, and so the credit spreads generated. Zhou (1997, 2001a) and Hilberink and Rogers (2002) deal with structural models in which the firm's asset value incorporates a jump component. While Zhou extends the Longstaff and Schwartz (1995) model considering a lognormally distributed jump component, Hilberink and Rogers (2002) opt for an extension of Leland (1994) and Leland and Toft (1996) using Levy processes, which only allow for down-

ward jumps in the firm's value. Both models avoid the problem of default predictability implying positive credit spreads for short maturities. Another characteristic of jump models is that they convert the recovery payment at default in a random variable, since the value of the firm can drop suddenly below the default threshold, whereas if the firm's value follows a diffusion process without jumps, the value of the firm at default, that is, what bondholders get, is always equal to the default threshold because of the continuity of the firm's value path.

Fouque, Sircar and Solna (2006) consider the effect of introducing stochastic volatility in FPM, finding that it increases short-term spreads.

Davydenko (2005) criticizes existing structural models because they obviate the liquidity reasons as the main determinants of default for some firms, particularly the ones with high external financing costs (p. 2):

Several default triggers have been proposed in structural models of debt pricing. Most models assume that a firm defaults when the market value of its assets falls below a certain boundary (Black and Cox, 1976; Leland, 1994). This default boundary may correspond to an exogenous net-worth covenant, or to the endogenously determined threshold at which equityholders are no longer willing to service debt obligations. Should the firm find itself in a liquidity crisis while its asset value is still above the boundary, equityholders in these models will always be willing and able to avoid default by raising outside financing. This approach contrasts with the assumption that firms default when current assets fall short of current obligations, due to either a minimum cash-flow covenant, or market frictions precluding the firm from raising sufficient new external financing (Kim et al., 1993; Anderson and Sundaresan, 1996). Models incorporating both value- and liquidity-based defaults are rare, and little empirical evidence is available to motivate the choice of the default trigger. If, in reality, default is triggered by different factors for different firms, existing models are likely to lack accuracy in predictions.

Davydenko (2005), using a sample of U.S. (speculative rating-grade) bond issuers from 1996 to 2003, shows that the importance of liquidity shortages in triggering default for a

particular firm depends on the firm's cost of external financing (p. 2): "firms with low costs of external financing default when the continuation value of assets is low. By contrast, if external funds are costly, a liquidity crisis may force reorganization even if the going-concern surplus is still substantial."²¹ Moreover, the author presents empirical evidence against the view that default is triggered when the asset value crosses a particular threshold.

Therefore, empirical evidence suggests that structural models need to be theoretically extended in order to incorporate the possibility of the firms defaulting because of liquidity shortages and high funding costs.

Estimation

The literature provides several ways of calibrating V_t and σ_V . The first method makes use of Ito's lemma to obtain a system of two equations in which the only two unknown variables are V_t and σ_V .²² Assume the firm's equity value follows a geometric Brownian motion under \mathbf{P} , with volatility σ_E :

$$dE_t = r E_t dt + \sigma_E E_t dW_t \quad (18)$$

Since the value of the equity is a function of time and of the value of the assets, $E_t = f(V_t, t)$, we can apply Ito's lemma to get

$$\begin{aligned} dE_t = & \left[\frac{\delta f(V_t, t)}{\delta t} + \frac{\delta f(V_t, t)}{\delta V_t} V_t r \right. \\ & \left. + \frac{1}{2} \frac{\delta^2 f(V_t, t)}{(\delta V_t)^2} (V_t \sigma_V)^2 \right] dt \\ & + \frac{\delta f(V_t, t)}{\delta V_t} V_t \sigma_V dW_t \end{aligned} \quad (19)$$

Comparing the coefficients multiplying the Brownian motion in the two previous equations we obtain the following identity

$$\sigma_E E_t = \frac{\delta f(V_t, t)}{\delta V_t} V_t \sigma_V \quad (20)$$

Noting that $\frac{\delta f(V_t, t)}{\delta V_t} = \frac{\delta E_t}{\delta V_t} = \Phi(d_1)$ and rearranging we obtain the first equation of the system:²³

$$\sigma_V = \frac{E_t}{V_t} \sigma_E \Phi(d_1) \quad (21)$$

The second equation results simply from matching the theoretical value of equity with the observed market price (\hat{E}_t):

$$E_t(V_t, \sigma_V, T - t) = \hat{E}_t \quad (22)$$

As we mentioned before, the only two unknowns in the system formed by the last two equations are V_t and σ_V .²⁴

Duan (1994) points out some drawbacks of the previous method. First, the method considers the equity volatility as constant and independent of the firm's asset value and time. Second, he claims that the first equation is redundant since it is used to derive the second equation. And third, the traditional method does not provide us with distribution functions, or even confidence intervals, for the estimates of V_t and σ_V .

Duan (1994) proposes another method of estimating V_t and σ_V , based on maximum likelihood estimation using equity prices and the one-to-one relationship between equity and asset levels given by (4).²⁵ Duan et al. (2004) follow the maximum likelihood approach introduced by Duan (1994) but, unlike previous works, they take into account the survivorship issue, by incorporating into the likelihood function the fact that a firm survived. They argue that (p. 3), "In the credit risk setting, it is imperative for analysts to recognize the fact that a firm in operation has by definition survived so far. Estimating a credit risk model using the sample of equity prices needs to reflect this reality, or runs the risk of biasing the estimator."

Duan and Fulop (2005) extend Duan's (1994) maximum likelihood estimation method to account for the fact that observed equity prices might be contaminated by trading noises. They find that taking into account trading noises generates lower estimates for the asset volatility σ_V

and therefore overestimates the firms' default probabilities.

Bruche (2005) describes how structural models can be estimated using a simulated maximum likelihood procedure, which allows us to use data on any of the firm's traded claims (bonds, equity, CDS, ...) as well as balance sheet information to improve the efficiency of the estimation. The paper explores the possibility of considering that not only equity, but the rest of the claims used in the estimation procedure can be priced with noise, showing that (p. 3) "even small amounts of noise can have serious consequences for estimation results when they are ignored."

A different way of estimating V_t and σ_V , which can be found in Jones et al. (1984), consists simply of estimating the asset value as the sum of the equity market value, the market value of traded debt, and the estimated value of nontraded debt. Provided with a time series for V_t we can estimate its volatility σ_V .

Hull, Nelken, and White (2004) propose a way to estimate the model's parameters from implied volatilities of options on the company's equity, avoiding the need to estimate σ_E and to transform the firm's debt structure into a zero-coupon bond. Using as inputs two equity implied volatilities and an estimate of the firm's debt maturity T , their model provides us with an estimate of σ_V and the leverage ratio $\frac{De^{-r(T-t)}}{V_t}$, which allows us to calculate E_t and the probability of default. We should note that to calculate the value of the debt $z(t, T) = V_t - E_t$ we still need an estimate for V_t .²⁶

We still have to estimate the default threshold K . Sundaram (2001) indicates that (p. 7) "default tends to occur in practice when the market value of the firm's assets drops below a critical point that typically lies below the book value of all liabilities, but above the book value of short-term liabilities." Thus, one approach is to choose a value for D between those two limits. Davydenko (2005) estimates the default threshold to be around 72% of the firm's face value of debt.

Liquidation Process Models

In FPM default occurs the first time the asset value goes below a certain lower threshold, that is, the firm is liquidated immediately after the default event; the default event corresponding to the crossing of the asset value through the lower barrier. In contrast with FPM, a new set of models considers the case where the default event does not immediately cause liquidation but it represents the beginning of a process, the liquidation process, which might or might not cause liquidation after it is completed. As explained earlier, we refer to these models as liquidation process models (LPM).

The distinction between the terms *default event* and *liquidation* must be clear to understand LPM and their differences with FPM. A default event takes place when the firm's asset value V_t goes below the lower threshold K (which can be exogenous, constant, time dependent, stochastic, or endogenously derived). A default event signals the beginning of a financially distressed period, which will not necessarily lead to liquidation. Liquidation takes place when the firm is actually liquidated, its activity stops, and its remainings are distributed among its claimholders.

In FPM described above the default event does coincide with liquidation.²⁷ However, as pointed out by Couderc and Renault (2005, p. 2), most liquidations "do not arise suddenly but are rather the conclusion of a long lasting process." As pointed out by Moraux (2004, p. 3): "Empirical studies in USA have found that additional 'survival' periods beyond the main default event last up to 3 years (Altman-Eberhart (1994), Betker (1995), Hotchkiss (1995)). Helwege (1999) reports that the longest default of modern US junk bond market is seven years long."²⁸

The fact that the liquidation process can take quite a while implies that when empirically studying the causes of liquidation past information shows up as a significant explanatory variable, together, of course, with contemporaneous

information, because it comprises information about the liquidation process. Information here refers to the firms' financial variables as well as financial markets, business cycle, credit markets, and default cycle indicators. Couderc and Renault (2005) use a database containing the rating history of over ten thousand firms for the period 1981–2003 and analyze, using duration models, whether past values of several financial markets (business cycle, credit markets, and default cycle) are relevant in explaining default probabilities in addition to their contemporaneous values. Their results show the critical importance of past information in default probabilities.

LPM extend FPM to account for the fact that the liquidation time takes place after (sometimes quite a lot after) the occurrence of a default event. François and Morellec (2004), Moraux (2004), and Galai, Raviv, and Wiener (2005) put forward a theoretical LPM.

François and Morellec (2004) argue that while in most of FPM the default event leads to an immediate liquidation of the firm's assets, firms in financial distress have several options to deal with their distress. First, under Chapter 7 of the U.S. Bankruptcy Code, they can liquidate its assets straight away. This possibility would fit FPM. However firms can also file for bankruptcy under Chapter 11 of the U.S. Bankruptcy Code and start a court-supervised liquidation process. The authors refer to existing literature (p. 390) to provide some evidence about the relevance of Chapter 11:

Upon default, the court grants the firm a period of observation during which the firm can renegotiate its claims. At the end of this period, the court decides whether the firm continues as a going concern or not.

Empirical studies show that most firms emerge from Chapter 11. Only a few firms (5%, according to Gilson, John, and Lang [1990] and Weiss [1990], and between 15% and 25%, according to Morse and Shaw [1988]) are eventually liquidated under Chapter 7 after filing Chapter 11. Why do some firms recover while others do not? It is generally acknowledged (see Wruck 1990 or White 1996) that there exist two types of defaulting firms. First,

firms that are economically sound promptly recover under Chapter 11. Default was only due to a temporary financial distress. Second, firms that are economically unsound keep on losing value under Chapter 11.²⁹

François and Morellec consider that, after a default event, i.e. after the asset value V_t goes below the lower threshold K , a firm is liquidated if and only if V_t remains below K consecutively during a period of time of a given length d (which in their numerical simulations they take to be two years). If a default event happens and the asset value remains under the lower threshold for a period lower than d , the liquidation process finishes and the firm continues in business as usual. The term consecutively in the definition of liquidation above means that the number of successfully managed past default events and liquidation periods³⁰ the firm has experienced does not affect the maximum length d of future liquidation periods.

The authors provide closed-form solutions for corporate debt and equity values and analyze the implications of the model for optimal leverage and credit spreads. Numerical simulations show that credit spreads are an increasing function of the length d .

Moraux (2004) extends the François and Morellec (2004) model including an additional cause of liquidation to François and Morellec's one (which they call liquidation procedure A). Under his proposed liquidation procedure, procedure B, liquidation happens when the total, that is, cumulative, time the firm's assets value stands under the default threshold exceeds d . The difference between procedures A and B lies in the words consecutively and cumulative, and Moraux (2004, p. 17) explains it clearly:

Under the procedure A, each time the firm value process passes through and above K , the liquidation procedure is closed and the hypothetical distress counter is set to zero. The next time a default event occurs, an identical procedure is run and an equal period of time d is granted. . . . Under the procedure B, the distress counter is never set to zero. Subsequent granted periods (and therefore tolerance) will be lower and lower as more default events and

long financial distress will be observed. In fact, the granted time is lowered (each time) by the duration just used.

Financial distress refers to the situation in which $V_t < K$. A firm can be liquidated by either one or the other liquidation procedures. Moraux (2004) shows that any liquidation procedure based on the time spent by the firm in financial distress is bounded by the procedures A and B in the sense that its implied liquidation date will be higher (lower) than the liquidation date implied by procedure B (A).

The author derives closed form solutions for different claims such as equity, different seniority debts, and convertible debt. In particular, the value of equity is derived as a down and out Parisian option written on the firm assets under liquidation procedure A and as a down and out cumulative call option under liquidation procedure B. Numerical simulations show that the value of equity is an increasing function of d , and that, unlike in François and Morellec (2004), credit spreads increase or decrease with d depending on the seniority of the debt.

Galai, Raviv, and Wiener (2005) represent a step forward in the refinement of LPM, proposing a model extending and including the two previous ones. They argue that in the two previous models, the only thing that matters for a firm to be liquidated is the amount of time it spends in financial distress (either successively or cumulatively), but they fail to (p. 5) “capture the following two common features of bankruptcy procedures: (i) Recent distress events may have a greater effect on the decision to liquidate a firm’s assets than old distress events. . . . (ii) Severe distress events may have greater effect on the decision to liquidate a firm than mild distress events.” To account for such two stylized facts, the authors propose a structural model in which a firm is liquidated when a state variable representing the cumulative weighted time period spent by the firm in distress exceeds d . At each time, the cumulative weighted time period is computed as a weighted average of the total time spent by

the firm in distress, weighted by (1) how far away in the past such distress occurred and (2) how severe was such a distress, where distress severity is measured as an increasing function of $\max\{0, K - V\}$.

Galai, Raviv, and Wiener’s model has as special cases models such as Merton (1974), Black and Cox (1976), Leland (1994), Fan and Sundaresan (2001), François and Morellec (2004), and Moraux (2004). As a consequence it represents a general LPM so far. They solve the model numerically using Monte Carlo simulation based on Parisian options and Parisian contracts techniques to value debt and equity. They provide a very intuitive comparison of the liquidation mechanics in their general model with François and Morellec’s and Moraux’s ones, showing that Moraux’s cumulative liquidation procedure (B) has too strong memory because far-away distress periods have the same impact on liquidation triggering as current ones.

Although theoretically very appealing, LPM have not, unlike FPM, been empirically tested, and remains a field for future research.

State Dependent Models

Another avenue for (so far) theoretical research within the structural approach consists of extending standard models with regime switching: Some of the model parameters are state-contingent. As we review below, states can represent the state of the business cycle or simply the firm’s external rating. Cash flows, bankruptcy costs, and funding costs might be state-dependent.

This branch of structural models is able to reduce the problems of predictability of defaults (and recovery) suffered by standard models because the firm is subject to exogenous changes of parameters, which affect its ability to generate cash flows or its funding costs, which are the main drivers of default probabilities.

Hackbarth, Miao, and Morellec (2004) and Elizalde (2005b) put forward two different

models illustrating the previous ideas. In both cases the authors provide closed form expressions for the value of equity and debt, whose solutions imply solving systems of ordinary differential equations.

In Hackbarth, Miao, and Morellec (2004) cash flows and recovery rates depend on the state of the business cycle. Cash flows x_t follow a geometric Brownian motion and are scaled by a business cycle scalar factor: They are higher in expansions $y_H x_t$ than in recessions $y_L x_t$, $y_H > y_L$. In the same way, bankruptcy costs are expressed as a state-dependent fraction $1 - \alpha$ of the firm's assets; again, the recovery rate in expansions α_H is higher than in recessions α_L , $\alpha_H > \alpha_L$. At each point in time, there is an exogenous probability of switching between recession and expansion. The default threshold is endogenously chosen by equityholders to maximize the value of equity, and it turns out to be higher in recessions: The firm defaults earlier in recessions than in expansions. Numerical examples illustrate the implications of the model for default thresholds, default clustering, optimal leverage (countercyclical), and credit spreads. As argued above the model is able to generate nontrivial short-term spreads.

Elizalde (2005b) develops a structural model which, although originally applied to banks, can be extended to any firm. In contrast with previous models, the firms' asset value is assumed to be unobserved by debtholders. Debtholders rely on the ratings published by rating agencies to set the debt's coupon as a function of those ratings. As a consequence, the firms' funding costs are contingent on their ratings. Rating agencies perform timely audits to firms, with a given frequency, to find out their risk and asset levels, which determine the rating. Switching from one rating to another implies changes in the cost of debt and, as a consequence, in the ability of the firm to repay it. As in Hackbarth, Miao, and Morellec (2004) the default threshold is chosen endogenously by equityholders and it is rating-dependent.

As described by Duffie (2005, p. 2772), "It has become increasingly common for bond issuers to link the size of the coupon rate on their debt with their credit rating, offering a higher coupon rate at lower ratings, perhaps in an attempt to appeal to investors based on some degree of hedging against a decline in credit quality." This embedded derivative is called a ratings-based step-up. The author illustrates an example of a ratings-based step-up bond issued by Deutsche Telecom in 2002 with coupon payments linked to the firm's rating. While Elizalde (2005b) derives the price of such a bond using a structural model, Duffie provides its pricing formula using an intensity model.³¹

Like LPM, state-dependent models have only been developed theoretically and their future success in credit risk modeling (if any) lies in their empirical applicability and their ability to replicate and predict credit spreads and default probabilities.

DEFAULT CORRELATION

To incorporate default dependencies between firms using structural models the literature has essentially relied on natural extensions of single firm's models, either Merton (1974) type models or FPM. We will start this section reviewing these extensions, under which the default dependences between firms are introduced through correlated asset processes.³² Giesecke (2004) and Giesecke and Goldberg (2004) suggest that the default correlation implied by the use of correlated firms' asset processes accounts for the dependence of the firms' credit quality on common macroeconomic factors, what they term cyclical default correlation, but it does not account for credit risk contagion across firms and periods of default clustering. In order to introduce the contagion correlation in the model, Giesecke (2004) and Giesecke and Goldberg (2004) propose a model in which the firms' default thresholds are dependent one to each other and are unknown to investors.

After reviewing Giesecke (2004) and Giesecke and Goldberg (2004) we present factor models, which express the value of the firms' assets as a function of several common factors, which generate the correlation, and an idiosyncratic factor.³³ Duan et al. (2002) and Hull and White (2001) present two alternative approaches to deal with default correlation in structural models.

Cyclical Default Correlation

The most natural way to introduce default dependencies between firms in structural models is by correlating the firms' asset processes.³⁴ Suppose we have $i = 1, \dots, I$ different firms with asset value processes given by

$$dV_{i,t} = rV_{i,t}dt + \sigma_{V_i} V_{i,t}dW_{i,t} \quad (23)$$

for $i = 1, \dots, I$, where $W_{1,t}, \dots, W_{I,t}$ are correlated Brownian motions. As in the single firm case, these models imply predictable defaults. One way of getting rid of the default predictability would be to introduce jump components in the firms' asset processes. Those jump components could be either correlated or uncorrelated across firms. Correlated jump components, besides making defaults unpredictable, would also account for credit risk contagion effects. The main problem lies in the calibration of the jump components.

Contagion Default Correlation

Cyclical default correlation does not account for all the credit risk dependence between firms. Giesecke (2004) and Giesecke and Goldberg (2004) extend structural models for default correlation to incorporate credit risk contagion effects. The default of one firm can trigger the default of related firms. Furthermore, default times tend to concentrate in some periods of time in which the probability of default of all firms is increased and which cannot be to-

tally, or even partially, explained by the firms' common dependence on some macroeconomic factors.

Contagion effects can arise in this setting by direct links between firms in terms of, for example, commercial or financial relationships. The news about the default of one firm has a big impact on the credit quality of other related firms, which is immediately reflected in their default probabilities.

In structural FPM we assume that investors have complete information about both asset processes and default thresholds, so they always know the nearness of default for each firm, that is, the distance between the actual level of the firm's assets and its default threshold.³⁵

Giesecke (2004) and Giesecke and Goldberg (2004) introduce contagion effects in the model by relaxing the assumption that investors have complete information about the default thresholds of the firms. In Giesecke (2004), bondholders do not have perfect information, neither about the thresholds nor about their joint distribution. However, they form a prior distribution, which is updated at any time one of such thresholds is revealed, which only happens when the corresponding firm defaults. In Giesecke (2004) investors have incomplete information about the firms' default thresholds but complete information about their asset processes. Giesecke and Goldberg (2005) extend that framework to one in which investors do not have information about the firms' asset values or about their default thresholds. In this case, default correlation is introduced through correlated asset processes and, again, investors receive information about the firms' asset and default barrier only when they default. Such information is used to update their priors about the distribution of the remaining firms' asset values and default thresholds.

The incomplete information about the level of the default thresholds and the fact that those levels are dependent among firms (through a copula function) generate the source of credit

risk contagion. Investors form a belief about the level of the firms' default thresholds. Each time one of the firms defaults, the true level of its default threshold is revealed, and investors use this new information to update their beliefs about the default thresholds of the rest of the firms. This sudden updating of the investors' perceptions about the default thresholds of the firm, and thus about the nearness of default for each firm, introduces the default contagion effects in the models.

This model allows for the introduction of default correlation both through dependencies between firms' asset values, cyclical default correlations, and through dependencies between firms' default barriers, contagion effects.

The major problem of this approach is to calibrate and estimate the default threshold copula. See Giesecke (2003) for some remarks on how to choose and calibrate that copula.

Factor Models

Factor models consider the firms' asset values as a function of a group of common factors, which introduce the default correlation in the model, plus a firm's specific factor:

$$V_{i,t} = \sum_{j=1}^J w_{i,j} Z_{j,t} + \epsilon_{i,t} \quad (24)$$

where Z_1, \dots, Z_J represent the common factors, $\epsilon_1, \dots, \epsilon_I$ the firms' specific factors (independent of Z_1, \dots, Z_J), and the correlation structure is given by the coefficient w . Once we know the realization of the common factors, the firms' asset value and thus the firms' default probabilities are independent.

The calibration of factor models is usually carried out by a logit or probit regression, depending on the assumptions about the distribution of the factors. Schönbucher (2000), Finger (1999), and Frey, McNeil, and Nyfeler (2001) present illustrations of these models.

KEY POINTS

- The structural approach for credit risk modeling considers the link between the credit quality of a firm and the firm's economic and financial conditions. As a consequence, defaults are endogenously generated within the models (instead of exogenously given as in reduced-form models). By relying on the firm's assets and liabilities to model default risk, structural models also provide a framework to analyze recovery rates.
- The structural literature on credit risk started with the Merton model, which used option pricing theory for valuing the debt of a firm. In the Merton model, the firm's capital structure is composed by equity and a zero-coupon. The firm is assumed to default at the bond maturity if the value of its assets is below the face value of the bond.
- The structural modeling approach has mainly developed by relaxing the strict assumptions of the Merton model, generating more realistic models, which take into account different characteristics of firms' capital structure, bankruptcy laws, macro variables, and so on.
- Structural models include first passage models, liquidation process models, and state-dependent models. In first passage models a default occurs the first time the firm's asset value goes below a certain lower threshold (related to the firm's level of debt). These models assume that the firm is liquidated immediately after the default event. Liquidation process models extend first passage models by taking into account the fact that firms that file for bankruptcy may avoid liquidation. Finally, state-dependent models assume that some of the parameters governing the firm's ability to generate cash flows or its funding costs depend on variables such as the business cycle (recession vs. expansion) or the firm's external rating.
- There are several ways to account for default correlation within the structural approach. Cyclical default correlation and factor

models consider the dependence of firms' credit quality on common macroeconomic factors. Contagion models include the dependence of firms' credit quality on other firms' credit quality.

NOTES

15. See, for example, Mello and Parsons (1992), Nielsen et al. (1993), Leland (1994), Anderson and Sundaresan (1996), Leland and Toft (1996), Mella-Barral and Perraudin (1997), and François and Morellec (2004).
16. For a discussion of strategic debt service, see Mella-Barral and Perraudin (1997), Fan and Sundaresan (2000), and references therein.
17. See Black and Cox (1976), Leland (1994), and Leland and Toft (1996) for models with constant interest rates, and see Kim, Ramaswamy, and Sundaresan (1993), Nielsen et al. (1993), Longstaff and Schwartz (1995), Briys and de Varenne (1997), Collin-Dufresne and Goldstein (2001), and Hsu,

- Saá-Requejo, and Santa-Clara (2004) for models with stochastic interest processes.
18. See Anderson and Sundaresan (2000), Eom, Helwege, and Huang (2003), and Ericsson and Reneby (2004).
 19. See Jones et al. (1984), Franks and Torous (1989), Sarig and Warga (1989), Fons (1994), Huang and Huang (2003), and Leland (2004).
 20. Elizalde (2005a) presents a review of structural models that appeared in the literature, which consider incomplete information assumptions and bridge the gap between the structural and the reduced approach.
 21. At any given point in time the firms' owners face a decision of whether to liquidate the firm, or to maintain the status quo by continuing operations under the current regime, also referred to as a going concern.
 22. See, for example, Jones et al. (1984), Ronn and Verma (1986), Eom et al. (2000), Delianedis and Geske (2003), and Ericsson and Reneby (2005).
 23. Crosbie and Bohn (2003) point out that this equation holds only instantaneously, and that in practice, market leverage, which would be represented here by $\frac{e^{-t(T-t)}D}{V_t}$, moves around far too much for that equation to provide reasonable results.
 24. Ronn and Verma (1986) extend the estimation to the cases of nonstationary σ_E and stochastic interest rates.
 25. For a complete description of this method see Duan (1994), Duan et al. (2002), and Ericsson and Reneby (2005), who also present a comparison with the traditional method.
 26. Eom et al. (2000) suggest another procedure to estimate σ_V , which they term the bond-implied volatility method.
 27. In fact, we called simply *default* to such an occurrence. In what follows we shall use the terms *default* and *liquidation* with the same meaning (different from default event!). A default event starts the process of liquidation. The process of liquidation has two possible endings: liquidation or default and reorganization (which happens when the firm manages to improve its financial health and avoid closure).
 28. See also Frank and Torous (1989) and Gilson (1997).
 29. See also Kahl (2001) and Morrison (2003).
 30. Successfully managed means that such liquidation periods did not last longer than d and, as a consequence, did not trigger liquidation.
 31. Manso, Strulovici, and Tchisty (2004) present an alternative derivation of ratings-based step-up bonds using structural models, and review the existing literature.
 32. See Zhou (2001b).
 33. See Schönbucher (2000), Finger (1999), and Frey, McNeil, and Nyfeler (2001).
 34. See Zhou (2001b).
 35. We are not considering here jump components in the dynamics of the assets processes.

Modeling Portfolio Credit Risk

SRICHANDER RAMASWAMY, PhD

Senior Economist, Bank for International Settlements, Basel, Switzerland

Abstract: Modeling credit risk is more challenging than modeling market risk. Some of these challenges relate to the differences in the conceptual approaches used for modeling credit risk and the data limitations associated with the estimation of key model parameters. Hence, there is invariably a subjective element to the modeling of credit risk. A better understanding of these subjective elements can help practitioners to exercise sound judgment and to raise the right questions when trying to interpret the statistical outputs provided by credit risk models.

This entry describes the building blocks to modeling credit risk. Key elements of the building blocks include probability of default of the issuer; recovery rate in the event of issuer default; and the probabilities of migrating to different credit rating states. Various techniques that can be employed to estimate the probability of issuer default, including their relative merits and limitations, are then discussed. Subsequently, the common approaches to quantifying credit risk are introduced. These include the default mode paradigm, which considers default and no default as two states of the world; and the migration mode paradigm, which includes migrations to other credit rating categories including the default state. The entry concludes with a numerical example to illustrate the various concepts presented.

ELEMENTS OF CREDIT RISK

Credit risk is the risk that a borrower will be unable to make payment of interest or principal in a timely manner. Under this definition, a delay in repayments, restructuring of borrower repayments, and bankruptcy, which constitute default events, will fall under credit risk. In addition to this, the mark-to-market loss of a bond resulting from a change in the market perception of the issuer to service the debt in future is also attributed to credit risk. This manifests itself in the form of a widening of the credit spread of the security in question against a risk-free asset, such as the Treasury bond, of similar maturity. The fluctuations in the credit spread between the two securities reflect views on the intrinsic creditworthiness of the issuer of the defaultable security.

The views expressed here are those of the author and not necessarily those of the Bank for International Settlements.

The key determinants of credit risk at the security level include *probability of default* (PD) of the issuer, that is, the probability that the issuer will default on its contractual obligations to repay its debt; *recovery rate* given that the issuer has defaulted; and *rating migration* probabilities, that is, the extent to which the credit quality of the issuer improves or deteriorates as expressed by a change in the probability of default of the issuer. The following sections discuss in greater detail these determinants of credit risk for corporate issuers, and wherever relevant, methods commonly employed to estimate them will be indicated.

Probability of Default

Assessments about an issuer's ability to service debt obligations play a fundamental role in establishing the level of credit risk embedded in a security. This is usually expressed through the default probability that quantifies the likelihood of the issuer not being able to service the debt obligations. Since probability of default is a function of the time horizon over which one measures the debt servicing ability, it is standard practice to assume a one-year time horizon to quantify this.

In general, the approaches used to determine default probabilities at the issuer level fall into two broad categories. The first is empirical in nature and requires the existence of a public credit-quality rating scheme. The second is based on Merton's options theory framework (Merton, 1974), and hence, is a structural approach. The empirical approach to estimating PD makes use of a historical database of corporate defaults to form a static pool of companies having a particular credit rating for a given year. Annual default rates are then calculated for each static pool, which are then aggregated to provide an estimate of the average historical default probability for a given credit rating. If one uses this approach, then the default probabilities for any two issuers having the same credit rating will be identical. The op-

tion pricing approach to estimate default probability makes use of the current estimates of the firm's assets, liabilities, and asset volatility, and hence, is related to the dynamics of the underlying structure of the firm. Each of these approaches is discussed below in greater detail.

Empirical Approach

The empirical approach to determining probability of default is taken by major rating agencies that include Moody's Investors Service, Standard & Poor's Corporation, and Fitch Ratings. The rating agencies assign credit ratings to different issuers on the basis of extensive analysis of both the quantitative and qualitative performance of a firm, which is intended to capture the level of credit risk. (How credit ratings are assigned is not discussed in this entry.) For purpose of illustrating the empirical approach used to determining default probabilities for different credit ratings, we will discuss Moody's methodology.

Moody's rating symbols (Aa, A, Baa, etc.) for issuer ratings are opinions of the ability of the issuer to honor senior unsecured financial obligations and contracts denominated in foreign and/or domestic currency. The rating gradations provide bondholders with a simple system to measure an issuer's ability to meet its senior financial obligations.

In addition to the generic rating categories, Moody's applies numerical modifiers 1, 2, and 3 for the rating categories from Aa to Caa. The modifier 1 indicates that the issuer is in the higher end of its letter-rating category; the modifier 2 indicates a mid-range ranking; the modifier 3 indicates that the issuer is in the lower end of the letter-ranking category. It is customary to refer to a rating change from grade Aa1 to Aa2 as a one-notch rating downgrade. Bonds issued by firms rated between Aaa to Baa are referred to as investment-grade bonds and the rest as non-investment-grade bonds.

It is important to emphasize here that Moody's ratings incorporate assessments of both the likelihood and the severity of default.

Considering that a particular issuer could have debt issues with different collateral and seniority, Moody's approach will lead to different debt issues of a particular issuer having different ratings. However, when an issuer is deemed to have defaulted on a particular debt issue, cross default clauses will require all outstanding debt of the issuer to be considered as having defaulted. This in turn brings us to the following question: What events signal the default of an issuer? Moody's definition of default considers three types of default events:

1. There is a missed or delayed disbursement of interest and/or principal including delayed payments made within a grace period.
2. An issuer files for bankruptcy or legal receivership occurs.
3. A distressed exchange occurs where (1) the issuer offers bondholders a new security or package of securities that amount to a diminished financial obligation, or (2) the exchange had the apparent purpose of helping the borrower to default.

One may note here that the above definitions of default are meant to capture events that change the relationship between the bondholder and bond issuer, which subjects the bondholder to an economic loss.

The empirical approach to determining probability of default relies on historical defaults of various rated issuers. This requires forming a static pool of issuers with a given rating every year and computing the ratio of defaulted issuers after a one-year period to the number of issuers that could have potentially defaulted for the given rating. If, during the year, ratings for certain issuers are withdrawn, then these issuers are subtracted from the potential number of issuers who could have defaulted in the static pool. Specifically, the one-year default rates for A-rated issuers during a given year represent the number of A-rated issuers that defaulted over the year divided by the number of A-rated issuers that could have defaulted over that year. Annual default rates calculated in this manner

for each rating grade are then aggregated to provide an estimate of the average historical default probability for a given rating grade.

We mentioned earlier in this entry that although different debt issues of a particular issuer could have different ratings assigned depending on the seniority of the issue, cross default clauses will require all outstanding debt of a particular issuer to default at the same time. This raises an important question when managing corporate bond portfolios, namely, whether the issuer rating or the rating of the bond issue is to be considered when implying the probability of default. The short answer to this question is that it depends on how credit risk will be quantified for the given bond. The approach taken here to quantify bond-level credit risk requires that the credit rating of the bond issuer is the one to be used. This will be evident when we discuss the quantification of credit risk at the bond level.

Merton's Approach

Merton's approach to estimating the probability of default of a firm builds on the limited liability rule that allows shareholders to default on their obligations while surrendering the firm's assets to the creditors. In this framework, the firm's liabilities are viewed as contingent claims on the assets of the firm, and default occurs at debt maturity when the firm's asset value falls below the debt value. Assuming that the firm is financed by means of equity S_t and a single zero-coupon debt maturing at time T with face value F and current market value B_t , the firm's assets at time t can be represented as

$$A_t = S_t + B_t \quad (1)$$

The probability of default in Merton's framework for the firm will be the probability that the firm's assets is less than the face value of the debt, which is given by,

$$PD = \text{prob}[A_T < F] \quad (2)$$

In order to determine PD in Merton's framework, we need to select a suitable model for the

process followed by A_t . Standard assumption is to postulate that A_t follows a log-normal process with growth rate μ and asset volatility σ_A which is given below:

$$A_t = A_0 \exp[(\mu - 0.5\sigma_A^2)t + \sigma_A\sqrt{t}z_t] \quad (3)$$

In equation (3) z_t is a normally distributed random variable with zero mean and unit variance. Using equation (3) in conjunction with equation (2) we can denote the PD as

$$PD = \text{prob}[\ln A_0 + (\mu - 0.5\sigma_A^2)T + \sigma_A\sqrt{T}z_T < \ln F] \quad (4)$$

In equation (4) we have taken logarithm on both sides of the inequality, since doing so does not change the probabilities. Rearranging the terms in equation (4), the probability of default for the firm can be represented as

$$PD = \text{prob} \left[z_T < -\frac{\ln \frac{A_0}{F} + (\mu - 0.5\sigma_A^2)T}{\sigma_A\sqrt{T}} \right] \quad (5)$$

Since z_T is a normally distributed random variable, PD can be represented as

$$PD = N(-D) \quad (6)$$

where

$$D = \frac{\ln \frac{A_0}{F} + (\mu - 0.5\sigma_A^2)T}{\sigma_A\sqrt{T}} \quad (7)$$

$$N(-D) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{-D} \exp(-\frac{1}{2}x^2)dx \quad (8)$$

In equation (7), D represents the distance to default, which is the distance between the logarithm of the expected asset value at maturity and the logarithm of the default point normalized by the asset volatility.

Although Merton's framework for determining PD for issuers is rather simple, applying this directly in practice runs into difficulties. This is because firms seldom issue zero coupon bonds and usually have multiple liabilities. Furthermore, firms in distress may be able to draw on lines of credit to honor coupon and principal

payments, resulting in a maturity transformation of their liabilities.

To resolve these difficulties Moody's KMV suggests some modifications to Merton's framework to make the default probability estimate meaningful in a practical setting (see Crosbie and Bohn, 2002). (Moody's KMV refers to probability of default as expected default frequency or EDFTM). For instance, rather than using face value of the debt to denote the default point, Moody's KMV suggests using the sum of the short-term liabilities (coupon and principal payments due in less than one year) and one-half of the long-term liabilities. This choice is based on the empirical evidence that firms default when their asset value reaches a level that is somewhat between the value of total liabilities and the value of short-term liabilities. Further, since the asset returns of the firms may in practice deviate from a normal distribution, Moody's KMV maps the distance to the default variable to a historical default statistics database to estimate the probability of default. In the KMV framework, default probabilities for issuers can take values in the range between 0.02% and 20%.

To illustrate the KMV approach, let DPT denote the default point, which is equal to the sum of the short-term liabilities due in less than one year and one-half of the long-term liabilities, and $E(A_T)$ the expected value of the firm's assets one year from now. Then the distance to default is given by,

$$D = \frac{\ln \frac{E(A_T)}{DPT}}{\sigma_A} = \frac{\ln \frac{A_0}{DPT} + (\mu - 0.5\sigma_A^2)T}{\sigma_A\sqrt{T}} \quad (9)$$

In equation (9), the market value of the firm's assets is not observed since liabilities of the firm are not traded. What can be observed in the market is the equity value of the firm because it is traded. Since the value of the firm's equity at time T can be seen as the value of a call option on the assets of the firm with a strike price equal to the book value of the liabilities, we have the

following equation:

$$S_T = A_T \times N(d_1) - e^{-rT} \times DPT \times N(d_2) \quad (10)$$

In equation (10), $N(\cdot)$ is cumulative standard unit normal distribution, r is the risk-free interest rate, and the variables d_1 and d_2 are given by,

$$d_1 = \frac{\ln(A_T/DPT) + (r + \frac{1}{2}\sigma_A^2)T}{\sigma_A\sqrt{T}} \quad (11)$$

$$d_2 = d_1 - \sigma_A\sqrt{T} \quad (12)$$

It is possible to show that equity and asset volatility are related through the following relation:

$$\sigma_S = \frac{A_T}{S_T} \times N(d_1) \times \sigma_A \quad (13)$$

From this relation it is possible to solve for the asset value and asset volatility, given the equity value and equity volatility using an iterative procedure. Knowing the asset volatility and asset value, it is possible to compute the distance to default using equation (9) from which probability of default can be inferred.

Relative Merits

The empirical and structural approaches to determine the probability of default for issuers can result in significant differences in the estimates of PD. Both approaches have their relative advantages and disadvantages. For instance, the empirical approach has the implicit assumption that all issuers having the same credit rating will have identical PD. Furthermore, this default probability will be equal to the historical average rate of default. Use of the structural approach, on the other hand, will result in PD being more responsive to changes in economic conditions and business cycles as it incorporates current estimates of the asset value and asset volatility of the firm in deriving this information. One drawback, however, is that the historical database of defaulted firms is comprised mostly of industrial corporates. As a consequence, use of the industrial corpo-

rate default database to infer the PD of regulated financial firms could potentially result in biased PD estimates. Seen from a trading perspective, credit spreads for corporates tend to be influenced much more by agency ratings and credit rating downgrades rather than EDF values. This has the implication that bond market participants tend to attach greater significance to rating agency decisions for pricing. For the purpose of modeling portfolio credit risk and selecting an optimal corporate bond portfolio to replicate the benchmark risk characteristics, we will demonstrate the usefulness of both approaches in the entries to follow.

On Rating Outlooks

Rating agencies provide forward-looking assessment of the creditworthiness of issuers over the medium term. Such forward-looking credit assessments of issuers are referred to as rating outlooks. Outlooks assess the potential direction of an issuer's rating or creditworthiness over the next six months to three years. A positive outlook suggests an improvement in credit rating, a negative outlook indicates deterioration in credit rating, and a stable outlook suggests a rating change is less likely to happen. Bond prices tend to react to changes in rating outlook although no actual change in credit rating has occurred. In particular, the impact on prices is much more significant if the issuer is Baa since a rating downgrade can result in the issuer being rated non-investment grade. Furthermore, if a particular sector (such as Telecom) is having a negative rating outlook, a change in rating outlook from stable to negative for an issuer in this sector can also have a significant effect on bond prices.

The above observations raise the following important question: Should a negative or a positive rating outlook for a given issuer be incorporated in our assessment of PD through a downgrade or upgrade before it has actually happened? The short answer to this question is no, primarily because our estimate of credit risk will incorporate the probability that credit

rating of issuers can change over time. Forcing a rating change for the issuer before it has actually happened may tend to bias our estimate of credit risk.

Captive Finance Companies

Large companies in most industrial sectors have captive finance subsidiaries. The principal function of any financial subsidiary is to support the sales of the parent's products. This function can make the finance company a critical component of the parent's long-term business strategy. In light of this close relationship between the captive finance company and its parent, credit ratings for both are usually identical. However, if the legal clauses guarantee that the parent company's bankruptcy does not automatically trigger the bankruptcy of the financial subsidiary, rating differences may exist between the parent company and its financial subsidiary. For the purpose of quantifying credit risk, we will use the actual credit rating of the financial subsidiary in the calculations.

Estimating the probability of default of financial subsidiaries on the basis of Merton's structural model can lead to difficulties. This is because the equity of the financial subsidiary may not be traded. For example, Ford Motor is traded whereas the financial subsidiary Ford Credit is not traded. Considering that the financing arm of major industrial corporates is vital to the survival of both the parent and the subsidiary, one can argue that the equity market takes this relationship into account when valuing the parent company. Under this argument, one can assign the same probability of default to both companies where only one of them is traded in the market.

Recovery Rate In the event of default, bondholders will not receive all of the promised coupon and principal payments on the bond. Recovery rate for a bond, which is defined as the percentage of the face value that can be recovered in the event of default, will be of natural interest to investors. Considering that

credit market convention is to ask how much of promised debt is lost rather than how much of it is recovered, the term "loss given default" (LGD), which is defined as one minus recovery rate, is also commonly used in the credit risk literature.

In general, estimating the recovery value of the bond in the event of default is rather complex. This is because the payments made to bondholders could take the form of a combination of equity and derivative securities, new debt, or modifications to the terms of the surviving debt. Considering that there may be no market for some forms of payments, it may not be feasible to measure the recovery value. Moreover, the amount recovered could take several months or even years to materialize and could potentially also depend on the relative strength of the negotiating positions. As a result, estimating historical averages of amounts recovered from defaulted debt will require making some simplifying assumptions.

Moody's, for instance, proxy the recovery rate with the secondary market price of the defaulted instrument approximately one month after the time of default. The motivation for such a definition is that many investors may wish to trade out of defaulted bonds, and a separate investor clientele may acquire these and pursue the legal issues related to recovering money from defaulted debt instruments. In this context, Moody's recovery rate proxy can be interpreted as a transfer price between these two investor groups.

Empirical research on recovery rates suggests that industrial sector, seniority of the debt, state of the economy, and credit rating of the issuer one year prior to default are variables that have significant influence on potential recovery rates. For example, during periods of economic downturns, the recovery rate is usually lower relative to historical averages. This has the implication that there is also a time dimension to the potential recovery rates. Differences in recovery rates for defaulted debt across industry sectors arise because the recovery amount will

depend on the net worth of the firm’s tangible assets. For instance, firms belonging to industrial sectors with physical assets such as public utilities have higher recovery rates compared to the industry-wide average. Empirical results also tend to suggest that issuers that were rated investment grade one year prior to default tend to have higher recovery values compared to issuers that were rated non-investment grade.

In order to incorporate the variations in the observed recovery rates over time and between issuers when quantifying credit risk, the standard deviation of recovery rates, denoted σ_{RR} , is taken into account. Including the uncertainty in recovery rates will have the effect of increasing credit risk at the issuer level. Common practice is to use beta distribution to model the observed variations in recovery rates. The advantage of choosing beta distribution is that it has a simple functional form dependent on two parameters that allows for high recovery rate outliers observed in the empirical data to be modeled. The beta distribution has support on the interval 0 to 1, and its density function is given by,

$$f(x, \alpha, \beta) = \begin{cases} \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1}, & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases} \tag{14}$$

where $\alpha > 0$, $\beta > 0$, and $\Gamma(\cdot)$ is the gamma function. The mean and variance of the beta distribution are given by,

$$\mu = \frac{\alpha}{\alpha + \beta} \tag{15}$$

$$\sigma^2 = \frac{\alpha \cdot \beta}{(\alpha + \beta)^2 \cdot (\alpha + \beta + 1)} \tag{16}$$

Table 1 shows the empirical estimates of recovery rates on defaulted securities covering

the period 1978 to 2001 based on prices at time of default. One can notice that senior secured debt recovers on average 53% of the face value of the debt whereas senior unsecured debt recovers only around 42% of face value. The standard deviation of the recovery rates for all seniority classes is roughly around 25%.

The empirical estimates for average recovery rates tend to vary somewhat depending on the data set used and the recovery rate definition. For instance, the study by Moody’s using defaulted bond data covering the period 1982–2008 suggest that mean recovery rates for senior secured bonds is 53%, for senior unsecured bonds is 32.4%, and for subordinated bonds is 23.5%.

In the numerical examples to be presented in this entry, we have assumed that the bonds under consideration are senior unsecured debt. Furthermore, we have assumed that the standard deviation of the recovery rate is 25% and the average recovery rate is 35%, which is closer to Moody’s estimate incorporating more recent default data.

Rating Migrations The framework for assessing the issuer’s PD comprised of estimating the probability associated with the issuer defaulting on its promised debt payments. In this framework, the issuer is considered to be in one of two states: its current rating or the default state. In practice, default is just one of many states to which the issuer’s rating can transition. Actions of rating agencies can result in the issuer’s rating being downgraded or upgraded by one or several notches. One can associate the concept of a state with each rating grade

Table 1 Recovery Rate Statistics on Defaulted Securities (1978–2001)

Bond Seniority	Number of Issuers	Median	Mean	Standard Deviation
Senior secured	134	57.42%	52.97%	23.05%
Senior unsecured	475	42.27%	41.71%	26.62%
Senior subordinated	340	31.90%	29.68%	24.97%
Subordinated	247	31.96%	31.03%	22.53%

Source: Altman, Resti, and Sironi (2001).

second row correspond to the one-year migration probabilities of an issuer that is currently rated Aa1.

Considering that Table 2 is representative of a typical rating transition matrix that credit agencies publish, one can draw interesting conclusions from the relative frequency of rating downgrades and upgrades from this table. For example, the rating transition matrix suggests that higher ratings have generally been less likely to be revised over one year than lower ratings. Another observation is that large and sudden rating changes occur infrequently. As one moves down the rating scale, the likelihood of a mult notch rating change increases.

Quantifying Credit Risk

In the previous section we identified the important variables that influence credit risk at the security level. In this section we will focus our attention on quantifying credit risk at the security level. Without loss of generality, it will be assumed that the security is a *corporate bond*. Most of us are familiar with the concept of risk in connection with financial assets. In broad terms, risk is associated with potential financial loss that can arise from holding the asset, the exact magnitude of which is difficult to forecast. As a result, it is common to describe the potential loss in value using an appropriate probability distribution whose mean and standard deviation serve as useful measures for risk quantification.

The above practice is well known in the equities market where investors focus on market risk that model variations in stock return. This leads us to quantifying the market risk measures through expected return and standard deviation of return. Under the assumption that equity returns are normally distributed, the realized return will lie within one standard deviation of the expected return with two-thirds probability.

Quantifying credit risk for a corporate bond is similar in principle. Unlike the case for eq-

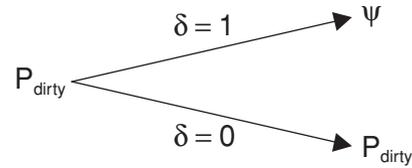

Figure 1 Typical Shape of the Credit Loss Distribution

uities, corporate bond investors focus on the distribution of potential losses that can result from the issuer-specific credit events. Borrowing the principle from equities market, it has become common practice to quantify credit risk at the security level through the mean and standard deviation of the loss distribution. However, there is an important difference between the two risk measures. This pertains to the distribution of credit loss, which unlike for market risk, is far from being a normal distribution. Hence, deviations from the expected loss by one standard deviation can occur more frequently than on one in three occasions. Credit market convention is to refer to the standard deviation of loss resulting from credit events as *unexpected loss* (UL) and the average loss as *expected loss* (EL). Figure 1 shows the typical shape of the distribution of credit losses.

In this section we will discuss how expected and unexpected loss used to quantify credit risk at the security or bond level can be determined. Depending on whether the loss distribution takes into account the changes in bond prices resulting from rating migrations, we can compute two sets of loss variables, one in the default mode and another in the migration mode. Quantification of credit risk in both these modes is discussed below.

Expected Loss Under Default Mode Expected loss under default mode of a bond is defined as the average loss the bondholder can expect to incur if the issuer goes bankrupt. Considering that default probability estimates are based on a one-year holding period, expected loss is also expressed over a one-year period. In

practice, the issuer could actually default at any time during the one-year horizon. Since a bond portfolio manager is usually interested in the worst-case loss scenario, which corresponds to the issuer defaulting in the immediate future, we will use the one-year PD to quantify the worst-case loss. This has the implication that we can quantify credit risk using the current trading price for the bond rather than its one-year forward price. Often, a portfolio manager's goal is to manage relative risk versus a benchmark. In this case, the use of one-year PD in conjunction with current trading prices will not bias the relative risk estimates. Moreover, this assumption leads to considerable simplification in quantifying credit risk since deriving forward yield curves for various credit ratings is quite tedious.

The estimate of expected loss for a security depends on three variables: probability of default of the issuer, the average recovery rate, and the nominal exposure (NE) to the security. One can think of the default process δ as being a Bernoulli random variable that takes the value 0 or 1. The value $\delta = 1$ signals a default and the value $\delta = 0$ signals no default. Conditional upon default, the recovery rate \Re is a random variable whose mean recovery rate is RR. Figure 2 pictorially depicts the default process and the recovery values. In this exhibit, P_{dirty} denotes the dirty price (clean price plus accrued interest) for a \$1 face value of the bond.

Figure 2 indicates that if the issuer defaults, the price of the bond will be equal to its recovery rate ψ , which is a random variable. If the issuer

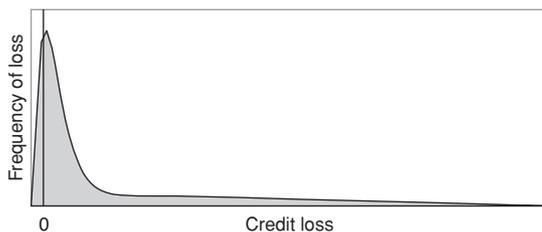

Figure 2 Bond Price Distribution Under Default Mode

does not default, the bond can be sold for a value equal to its current dirty price P_{dirty} . In this default mode framework, the price of the risky debt can be written as,

$$\tilde{P} = P_{dirty} \times I_{[\delta=0]} + \psi \times I_{[\delta=1]} \quad (17)$$

In equation (17), I is the indicator function of the default process. For the purpose of quantifying credit risk, the variable of interest to us is the credit loss resulting from holding the corporate bond. This is a random variable, which we denote $\tilde{\ell}$, and is given by,

$$\begin{aligned} \tilde{\ell} &= P_{dirty} - \tilde{P} = P_{dirty} - P_{dirty} \\ &\quad \times I_{[\delta=0]} - \psi \times I_{[\delta=1]} \end{aligned} \quad (18)$$

Taking expectations on both sides of equation (18) will allow us to compute the expected loss arising from credit risk. This is given by,

$$\begin{aligned} EL &= E(\tilde{\ell}) = P_{dirty} - P_{dirty} \\ &\quad \times (1 - PD) - E(\psi \times I_{[\delta=1]}) \end{aligned} \quad (19)$$

We note that computing expected loss requires taking the expectation of the product of two random variables, the recovery rate process and the default process. Knowledge of the joint distribution of these two random variables will be required to compute this expectation. Most credit risk models will make the simplifying assumption that these two random variables are independent. If we make this assumption, we get the equation for expected loss as given below:

$$\begin{aligned} EL &= P_{dirty} \times PD - RR \times PD \\ &= PD \times (P_{dirty} - RR) \end{aligned} \quad (20)$$

We remind the reader that P_{dirty} is the dirty price of the bond for \$1 nominal and RR in equation (20) is the mean recovery rate, which is expressed as a fraction of the face value of the debt. It is important to draw attention to the fact that the quantity $(P_{dirty} - RR)$ is different from LGD, which is defined as one minus the recovery rate. We therefore introduce the term "loss on default" (LD) to capture this new quantity as given below:

$$LD = P_{dirty} - RR \quad (21)$$

We note that loss on default will be identical to the quantity loss given default if the dirty price of the bond is equal to one. In all other circumstances these two quantities will not be the same.

Equation (20) has been derived under the assumption that the nominal exposure is one dollar. The expected loss from credit risk for a nominal exposure equal to NE is given by,

$$EL = NE \times PD \times LD \quad (22)$$

The use of the quantity LD rather than LGD in defining expected loss might raise some doubts in the minds of the reader. To clear these doubts, let us consider the following example that illustrates why LD is more appropriate than LGD in the context of bond portfolio management.

Let us consider the case of a bond portfolio manager who has the option to invest \$1 million either in a bond with dirty price \$100 (issuer A) or in a bond with dirty price \$80 (issuer B). In the latter case, the portfolio manager will buy \$1.25 million nominal value of issuer B's bond to fully invest the \$1 million. Let us assume that both issuers default within the next year and the recovery value is \$50 for \$100 face value of exposure. If the portfolio manager had invested in issuer A's bond, he would recover \$500,000 since the nominal exposure is \$1 million. On the other hand, if the portfolio manager invested in issuer B's bond, then the amount recovered would be \$625,000. This is because the portfolio manager has a nominal exposure of \$1.25 million of issuer B's bond. Clearly, from the portfolio manager's perspective the credit loss resulting from an investment in issuer A's bond is \$500,000, whereas the credit loss from an investment in issuer B's bond is only \$375,000, although both investments recovered 50% of the face value of debt. Use of the quantity LD correctly identifies the losses in both circumstances whereas the LGD definition will indicate that the losses are \$500,000 for issuer A's bond and \$625,000 for issuer B's bond. In practice, LGD is used in conjunction with the exposure amount of the transaction to identify the expected loss. How-

ever, this definition will also incorrectly identify the losses as being identical for both bonds in this example.

Unexpected Loss Under Default Mode We learned that the expected loss on the bond is the average loss that the investor can expect to incur over the course of a one-year period. However, the actual loss may well exceed this average loss over certain time periods. The potential deviation from the expected loss that the investor can expect to incur is quantified in terms of the standard deviation of the loss variable defined in equation (18). Credit market convention is to refer to the standard deviation of loss as unexpected loss. Hence, to derive the unexpected loss formula, we need to compute the standard deviation of the random variable $\tilde{\ell}$. To facilitate this computation, we will rewrite equation (18) as follows:

$$\begin{aligned} \tilde{\ell} &= P_{dirty} - P_{dirty} \times (1 - I_{[\delta=1]}) + \psi \times I_{[\delta=1]} \\ &= I_{[\delta=1]} \times (P_{dirty} - \psi) \end{aligned} \quad (23)$$

Recalling a standard result from probability theory, the variance of any random variable z can be written as the difference between the expected value of the random variable squared minus the square of its expected value. In equation form this is given by,

$$\sigma_z^2 = E(z^2) - [E(z)]^2 \quad (24)$$

We will again make the simplifying assumption that the default and recovery rate processes are independent in deriving the unexpected loss formula. Under this assumption the variance of the random variable $\tilde{\ell}$ can be written as,

$$\begin{aligned} Var(\tilde{\ell}) &= E(I_{[\delta=1]}^2) \times E[(P_{dirty} - \psi)^2] \\ &\quad - [E(I_{[\delta=1]})]^2 \times [E(P_{dirty} - \psi)]^2 \end{aligned} \quad (25)$$

Taking expected values and using the relation (24), equation (25) simplifies to,

$$Var(\tilde{\ell}) = [\sigma_{PD}^2 + PD^2] \times [\sigma_{RR}^2 + LD^2] - PD^2 \times LD^2 \quad (26)$$

In the above equation, σ_{PD}^2 is the variance of the Bernoulli random variable δ , which is given by

$$\sigma_{PD}^2 = PD \times (1 - PD) \quad (27)$$

Simplifying the terms in equation (26), it can be shown that unexpected loss, which is the standard deviation of the loss variable, is given by

$$UL = \sqrt{PD \times \sigma_{RR}^2 + LD^2 \times \sigma_{PD}^2} \quad (28)$$

The above formula for unexpected loss assumes that the nominal exposure is equal to one dollar. For a nominal exposure equal to NE, the unexpected loss at the security level will be given by

$$UL = NE \times \sqrt{PD \times \sigma_{RR}^2 + LD^2 \times \sigma_{PD}^2} \quad (29)$$

On the Independence Assumption

In deriving the expressions for expected and unexpected losses on a bond resulting from credit risk, we made the simplifying assumption that the default process and recovery rate process are independent. The question we should ask ourselves is whether this assumption is a reasonable one to make. Examining existing theoretical models on credit risk does not give us a definitive answer to this question. For instance, in Merton's framework the default process of a firm is driven by the value of the firm's assets. The risk of a firm's default is therefore explicitly linked to the variability in the firm's asset value. In this setup both the default process and the recovery rate are a function of the structural characteristics of the firm, and one can show that PD and RR are inversely related.

The reduced-form models, unlike structural models, do not condition default on the value of the firm. The default and recovery processes are modeled independently of the structural features of the firm and are further assumed to be independent of each other. This independence assumption between default and recovery processes, which is fundamental to reduced-form

models, is pervasive in all existing credit value at risk models.

Empirical results on the relationship between default and recovery values tend to suggest that these two variables are negatively correlated. The intuition behind this result is that both default rate and recovery rate may depend on certain structural factors. For instance, if a borrower defaults on the debt payments, the recovery rate will depend on the net worth of the firm's assets. This net worth, which is usually a function of prevailing economic conditions, will be lower during periods of recession. On the contrary, during recession the probability of default of issuers tends to increase. The combination of these two effects will result in a negative correlation between default and recovery rates.

Empirical research on the relationship between default and recovery rate processes suggests that a simple microeconomic interpretation based on supply and demand tends to drive aggregate recovery rate values. In particular, during high default years the supply of defaulted securities tends to exceed demand, which in turn drives secondary market prices down. Considering that RR values are based on bond prices shortly after default, the observed recovery rates are lower when there is an excess supply of defaulted securities.

In order to incorporate the empirical evidence that recovery values decrease when default rates are high, we will have to identify periods when PD is high relative to normal levels. If PD values are determined on the basis of historical average default rates as is done by rating agencies, it is difficult to distinguish between low and high default periods. On the other hand, if a structural approach is used to estimate PD values as is done by KMV Corporation, it is possible to signal periods when PD values are higher than historical average levels. This information can then be incorporated to determine the appropriate recovery rates to be used. Such an approach will amount to the use of a regime-switching model to determine the average recovery rates.

Expected Loss Under Migration Mode

To derive the formula for expected loss under default mode we took into consideration the credit event that results in the issuer defaulting on debt payments. In general, this is not the only credit event the bondholder will experience that influences the market price of the bond. More frequent are credit events that result in rating upgrades or downgrades of the bond issuer. These credit events correspond to a change in the opinion of the rating agencies concerning the creditworthiness of the issuer. Since rating changes are issuer-specific credit events, the associated bond price changes will fall under credit risk. Including price risk resulting from rating migrations in the calculation of potential credit losses is referred to as credit risk under migration mode.

In practice, the change in bond price can be both positive and negative depending on whether the rating change results in an upgrade or downgrade, respectively. However, we will use the term “credit loss” generically to refer to a change in bond price as a result of a credit event. Before proceeding to derive the formula that quantifies expected loss under migration mode, we will indicate how the price change resulting from a credit event can be estimated.

Estimating Price Changes Practitioners familiar with pricing of corporate bonds know that the issuer’s rating does not fully explain yield differentials between bonds of similar maturities. In an empirical study, Elton, Gruber, Agrawal and Mann (2002) find that pricing errors can vary from 34 cents per \$100 for Aa financials to over \$1.17 for Baa industrials. Their study suggests that the following factors have an important influence on observed price differentials between corporate bonds:

- The finer rating categories introduced by the major rating agencies when combined with the bond’s maturity
- Differences between Standard and Poor’s and Moody’s ratings for the issuer
- Differences in expected recovery rate for the bond
- The coupon on the bond due to different tax treatment
- Whether the bond is new and has traded for more than one year

These observations indicate that we cannot use generic yield curves for various rating grades to reprice bonds when the issuer’s rating changes. We will have to adopt a different technique to estimate the price risk resulting from rating changes. It is important to bear in mind that in the context of credit risk quantification, our objective is to estimate approximate price changes from rating migrations rather than to capture the correct trading price for the bond. To this end, rating migrations should result in a price change that is consistent with perceived change in the creditworthiness of the issuer.

The technique we will adopt here to estimate the change in bond price due to a rating change makes use of the current modified duration and convexity of the bond. To determine the change in yield associated with a rating change, we will assume that there exists a fixed yield spread between each rating grade that is a function of the debt issue’s seniority. These yield spreads will be taken relative to the government yield curve. If we denote modified duration of the bond by D and convexity by C , then the change in price of the bond due to a change Δy in the bond yield as a result of the rating change is given by,

$$\begin{aligned} \text{Price change} = & -P_{\text{dirty}} \times D \times \Delta y + 0.5 \\ & \times P_{\text{dirty}} \times C \times \Delta y^2 \end{aligned} \quad (30)$$

Considering that our interest is to estimate the loss resulting from the rating change to quantify credit risk, the following equation is the one that is relevant to us:

$$\Delta P = P_{\text{dirty}} \times D \times \Delta y - 0.5 \times P_{\text{dirty}} \times C \times \Delta y^2 \quad (31)$$

The advantage of such a technique is that it will retain price differentials observed in the market between bonds with similar maturity

Table 3 Example Yield Spreads for Different Rating Grades and Debt Seniority

Rating Grade	Rating Description	Senior Unsecured	Subordinated
1	Aaa / AAA	15 bp	20 bp
2	Aa1 / AA+	30 bp	40 bp
3	Aa2 / AA	45 bp	60 bp
4	Aa3 / AA-	60 bp	80 bp
5	A1 / A+	75 bp	100 bp
6	A2 / A	90 bp	120 bp
7	A3 / A-	105 bp	140 bp
8	Baa1 / BBB+	130 bp	180 bp
9	Baa2 / BBB	155 bp	220 bp
10	Baa3 / BBB-	180 bp	260 bp
11	Ba1 / BB+	230 bp	330 bp
12	Ba2 / BB	280 bp	410 bp
13	Ba3 / BB-	330 bp	480 bp
14	B1 / B+	430 bp	610 bp
15	B2 / B	530 bp	740 bp
16	B3 / B-	630 bp	870 bp
17	Caa-C / CCC	780 bp	1040 bp

and credit rating when the issuer migrates to a different rating grade. Table 3 shows the indicative yield spreads relative to government bonds for different rating grades as a function of the seniority of the debt issue. These yield spreads will be used to illustrate how the price change resulting from a rating migration can be estimated by using it in conjunction with the current duration and convexity of the bond.

Deriving Expected Loss

Unlike in the case of the default mode, the issuer can migrate to one of several rating grades under the migration mode during the course of the year. Associated with these rating migrations are discrete transition probabilities that comprise the rows of the rating transition matrix given in Table 2. In the rating migration framework, the transition probabilities represent historical averages and can be treated as deterministic variables. The random variables here are the credit losses that the bondholder incurs when the issuer rating changes. The expected value of the credit loss for a rating change from the i th grade to the k th grade is given by,

$$\Delta P_{ik} = P_{dirty} \times D \times \Delta y_{ik} - 0.5 \times P_{dirty} \times C \times \Delta y_{ik}^2 \quad (32)$$

In equation (32), Δy_{ik} denotes the yield change when the issuer rating changes from grade i to grade k . When the issuer migrates to the default state, the credit loss ΔP_{ik} will be equal to the loss on default LD. Considering that there are 18 rating grades including the default state, the expected loss under the rating migration mode for an issuer whose current credit rating is i is given by,

$$EL = \sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \quad (33)$$

In equation (33), p_{ik} denotes the one-year transition probability to migrate from rating grade i to rating grade k . The above equation quantifies the expected loss over a one-year horizon for a nominal exposure of one dollar. For a nominal exposure NE, the expected loss under migration mode is given by,

$$EL = NE \times \sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \quad (34)$$

Unexpected Loss Under Migration Mode

By definition, unexpected loss under migration mode is the standard deviation of the credit loss

variable. The loss variable under the migration mode is given by,

$$\tilde{\ell} = \sum_{k=1}^{18} p_{ik} \times \Delta \tilde{P}_{ik} \quad (35)$$

In equation (35), $\Delta \tilde{P}_{ik}$ denotes the credit loss when the credit rating changes from grade i to grade k , which is regarded as a random variable. The expected value of this random variable is ΔP_{ik} , and we shall denote its variance by σ_{ik}^2 . When k is equal to the default state, σ_{ik} will be equal to σ_{RR} , which is the standard deviation of the recovery rate. Recalling equation (24), we can write the variance of the loss variable as,

$$\begin{aligned} \text{Var}(\tilde{\ell}) &= E \left(\sum_{k=1}^{18} p_{ik} \times \Delta \tilde{P}_{ik}^2 \right) \\ &\quad - \left[E \left(\sum_{k=1}^{18} p_{ik} \times \Delta \tilde{P}_{ik} \right) \right]^2 \end{aligned} \quad (36)$$

Taking expectations and making use of the relation (24) once more, we get the following expression for the variance of the loss variable:

$$\begin{aligned} \text{Var}(\tilde{\ell}) &= \sum_{k=1}^{18} p_{ik} \times (\Delta P_{ik}^2 + \sigma_{ik}^2) \\ &\quad - \left[\sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \right]^2 \end{aligned} \quad (37)$$

If we assume that there is no uncertainty associated with the credit losses except in the default state, all σ_{ik}^2 terms in equation (37) will drop out other than σ_{RR}^2 . Making this assumption and noting that p_{ik} is equal to PD when k is the default state, the unexpected loss under migration mode for a nominal exposure NE is given by,

$$\begin{aligned} UL &= NE \\ &\times \sqrt{PD \times \sigma_{RR}^2 + \sum_{k=1}^{18} p_{ik} \times \Delta P_{ik}^2 - \left[\sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \right]^2} \end{aligned} \quad (38)$$

Numerical Example

In this section we will consider a numerical example to illustrate the computations of ex-

Table 4 Security Level Details of the Example Bond

Description	Value
Issuer rating grade	A3
Dirty price for \$1 nominal	1.0533
Nominal exposure	\$1,000,000
Modified duration	4.021
Convexity	19.75
Mean recovery rate	35%
Volatility of RR	25%

pected and unexpected losses under the default mode and migration mode. The security level details of the example we will consider are given in Table 4.

Since the mean recovery rate is assumed to be 35%, the loss on default for this security is equal to 0.7033 for one-dollar nominal exposure. The probability of default for this security is equal to 0.10%, which corresponds to the last column in row A3 of the transition matrix given in Table 3. The expected and unexpected losses in the default mode when PD = 0.001 are given below.

$$\begin{aligned} EL &= NE \times PD \times LD \\ &= 1,000,000 \times 0.001 \times 0.7033 = \$703.3 \\ UL &= NE \times \sqrt{PD \times \sigma_{RR}^2 + LD^2 \times \sigma_{PD}^2} \\ &= 1,000,000 \\ &\quad \times \sqrt{0.001 \times 0.25^2 + 0.7033^2 \times 0.001 \times (1 - 0.001)} \\ &= \$22,369.3 \end{aligned}$$

Under the migration mode, the breakdown of the calculations involved in estimating expected and unexpected losses are given in Table 5.

The expected loss under migration mode is given by,

$$\begin{aligned} EL &= NE \times \sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \\ &= 1,000,000 \times 0.003132 = \$3,132 \end{aligned}$$

The unexpected loss under migration mode is given by,

$$\begin{aligned} UL &= NE \\ &\times \sqrt{PD \times \sigma_{RR}^2 + \sum_{k=1}^{18} p_{ik} \times \Delta P_{ik}^2 - \left[\sum_{k=1}^{18} p_{ik} \times \Delta P_{ik} \right]^2} \\ &= 1,000,000 \\ &\quad \times \sqrt{0.001 \times 0.25^2 + 6.803 \times 10^{-4} - 0.003132^2} \\ &= \$27,073.8 \end{aligned}$$

Table 5 Calculation of EL and UL Under Migration Mode

Grade	P_{ik}	Δy_{ik}	ΔP_{ik}	$P_{ik} \times \Delta P_{ik}$	$P_{ik} \times \Delta P_{ik}^2$
1	0.05%	-0.90%	-0.0390	-0.000019	7.590E-07
2	0.11%	-0.75%	-0.0323	-0.000036	1.151E-06
3	0.05%	-0.60%	-0.0258	-0.000013	3.325E-07
4	0.24%	-0.45%	-0.0193	-0.000046	8.912E-07
5	1.55%	-0.30%	-0.0128	-0.000198	2.539E-06
6	8.68%	-0.15%	-0.0064	-0.000553	3.529E-06
7	75.40%	0.00%	0.0000	0.000000	0.000E+00
8	7.03%	0.25%	0.0105	0.000740	7.785E-06
9	3.83%	0.50%	0.0209	0.000801	1.676E-05
10	1.50%	0.75%	0.0312	0.000468	1.458E-05
11	0.57%	1.25%	0.0513	0.000293	1.501E-05
12	0.20%	1.75%	0.0709	0.000142	1.006E-05
13	0.23%	2.25%	0.0900	0.000207	1.864E-05
14	0.35%	3.25%	0.1267	0.000443	5.615E-05
15	0.05%	4.25%	0.1612	0.000081	1.299E-05
16	0.05%	5.25%	0.1937	0.000097	1.876E-05
17	0.01%	6.75%	0.2385	0.000024	5.688E-06
18	0.10%		0.7033	0.000703	4.946E-04
			Sum	0.003132	6.803E-04

It is useful to note here that under migration mode the expected loss is more than four times higher. The increase in the unexpected loss in migration mode is, however, only around 21% higher than the unexpected loss under default mode.

KEY POINTS

- Approaches used to determine default probabilities at the issuer level fall under two broad categories: the empirical approach that uses historical default data and public credit rating schemes; and the structural approach that uses options theory framework.
- Recovery rates on defaulted bonds vary over the business cycle and across industry sectors; and there is a negative relationship between recovery rates and probability of default.
- Credit risk for a corporate bond can be quantified in terms of the first

two moments of its loss distribution: expected loss and unexpected loss.

- Approaches to quantifying credit risk fall under two categories: those that are based on two states of the world, namely default or no default; and those that include migrations to other credit rating categories including the state of default.

Simulating the Credit Loss Distribution

SRICHANDER RAMASWAMY, PhD

Senior Economist, Bank for International Settlements, Basel, Switzerland

Abstract: Monte Carlo methods have become a valuable computational tool in modern finance as the increased availability of powerful computers has enhanced their efficiency. A particularly useful feature of Monte Carlo methods is that their computational complexity increases linearly with the number of variables. Moreover, they are flexible and easy to implement for a range of distributional assumptions for the underlying variables that influence the outcomes of interest. Monte Carlo methods are particularly effective for simulating credit loss distribution and for evaluating tail risk measures, and they are computationally less intensive than analytical methods.

The distribution of portfolio *credit risk* is highly skewed and has a long fat tail. Unlike the case for a normally distributed loss distribution, knowledge of the first two moments of the credit loss distribution provides little information about *tail risk*. To compute tail risk (large losses that occur with a low probability) one has to simulate the credit loss distribution using Monte Carlo techniques. In this entry we will provide a brief introduction to Monte Carlo methods and subsequently describe the computational process involved in performing a Monte Carlo simulation to generate the distribution of credit losses. Simulating the credit loss distribution is discussed under the assumption that the asset returns that drive credit events are either multivariate normal or multivariate *t* distributed. The discussion and the examples cited

in this entry assume that the credit risk arises from holding a portfolio of *corporate bonds*.

MONTE CARLO METHODS

Numerical methods known as *Monte Carlo methods* can be loosely described as statistical simulation methods that make use of sequences of random numbers to perform the simulation. The first documented account of Monte Carlo simulation dates back to the 18th century when a simulation technique was used to estimate the value π . However, it is only since the digital computer era that this technique has gained scientific acceptance for solving complex numerical problems in various disciplines. The name “Monte Carlo” was coined by Metropolis

The views expressed here are those of the author and not necessarily those of the Bank for International Settlements.

during the Manhattan Project of World War II because of the similarity of statistical simulation to games of chance symbolized by the capital of Monaco. Von Neumann laid much of the early foundations of Monte Carlo simulation that require generation of pseudo-random number generators and inverse cumulative distribution functions. The application of Monte Carlo simulation techniques to finance was pioneered by Phelim Boyle (1977) in connection with pricing of options.

It is tempting to think of Monte Carlo methods as a technique to simulate random processes that are described by a stochastic differential equation. This belief stems from the option pricing applications of Monte Carlo methods in finance where the underlying variable of interest is the evolution of stock prices that are described by a stochastic differential equation. However, this description is too restrictive because many Monte Carlo applications have no apparent stochastic content, such as the evaluation of a definite integral or inversion of a system of linear equations. In many applications of Monte Carlo methods, the only requirement is that the physical or mathematical quantity of interest to us can be described by a probability distribution function.

Monte Carlo methods have become a valuable computational tool in modern finance to price complex derivative securities and to perform value at risk calculations. An important advantage of Monte Carlo methods is that they are flexible and easy to implement. Further, the increased availability of powerful computers has enhanced the efficiency of these methods. Notwithstanding this, the method can still be slow and standard errors of estimates can be large when applied to high-dimensional problems or if the region of interest to us is not around the mean of the distribution. In such cases, we require a large number of simulation runs to estimate the variable of interest with reasonable accuracy. The standard errors on the estimated parameters can be reduced using conventional variance reduction procedures

such as control variate techniques or antithetic sampling approaches.

More recent techniques to speed up the convergence of Monte Carlo methods for high-dimensional problems make use of deterministic sequences rather than random sequences. These sequences are known by the name quasi-random sequences in contrast to the pseudo-random sequences commonly used in standard Monte Carlo methods. The advantage of using quasi-random sequences is that they generate sequences of n -tuples that fill n -dimensional space more uniformly than uncorrelated points generated by pseudo-random sequences. However, the computational advantage of quasi-random sequences diminishes as the number of variables increases beyond 30.

An important advantage of Monte Carlo methods is that the computational complexity increases linearly with the number of variables. In contrast, the computational complexity increases exponentially in the number of variables for discrete probability tree approaches for solving similar kinds of problems. This point is best illustrated by considering the problem of credit loss simulation. One approach to computing the loss distribution of a two-bond portfolio is to enumerate all possible combination of credit states this portfolio can be in one year's time. Assuming there are 18 possible credit states that each bond can be in, the two-bond portfolio could take one of 324 (18 times 18) credit states. Valuing the credit loss associated with each one of the 324 states will allow us to derive the credit loss distribution of the two-bond portfolio. If the number of bonds in the portfolio increases to 10, the total number of possible credit states will be equal to 18 to the power 10, which is equal to 3.57×10^{12} credit states. Clearly, even with such a small portfolio, it is practically impossible to enumerate all the states and compute the credit loss distribution.

If we use Monte Carlo simulation, on the other hand, the problem complexity remains the same irrespective of whether the portfolio is comprised of 2, 10, or more bonds. In each of these

cases we may wish to run several scenarios, each of which corresponds to a simulation run, and under each scenario compute the credit loss associated with the portfolio. Performing many simulation runs will allow us to compute the credit loss distribution of the bond portfolio. As the number of bonds in the portfolio increases, the computational effort involved increases linearly in the number of bonds in the portfolio.

The basic building blocks for performing Monte Carlo simulation will require a scheme to generate uniformly distributed random numbers and a suitable transformation algorithm if the probability distribution of the variable simulated is different from a uniform distribution. Most applications in finance require the generation of a normally distributed random variable. To simulate such a random variable, the standard transformation techniques used are either the Box-Muller method or the inverse cumulative normal method. If the simulated random variables are greater than one, we need methods to generate correlated random numbers that model the relationship between the variables.

Credit Loss Simulation

At the security level, credit loss arises from credit events that include rating migrations and outright default. As these credit events are associated with changes in perceptions about an obligor's ability to make the contractual debt payments, one needs to identify variables that influence the obligors' ability to pay. The variable that is often used in practice is the asset returns of the obligor. The motivation for using asset returns is that changes in asset values of a firm influence its solvency position. When asset values fall below outstanding liabilities, the firm is no longer considered solvent. But other thresholds based on rating transition probabilities can be derived and used to infer how changes in asset values will influence credit ratings. Simulating asset returns and checking their values against these thresholds

will allow us to signal credit events, which can then be used to estimate the credit loss for a particular simulation run.

Computing portfolio credit risk requires extending the above approach to model joint rating migrations, which in turn requires modeling the comovement of asset returns of different obligors. Considering that the marginal distribution of asset returns is assumed to be normal in Merton's option pricing framework (Merton, 1974), one can make a simplifying assumption that the joint distribution of asset returns is multivariate normal. The joint evolution of the asset returns of the obligors under the multivariate normal distribution will signal how the value of the portfolio evolves, or equivalently, what the credit loss on the portfolio will be. The distribution of obligor asset returns under the multivariate normal distribution can be generated using Monte Carlo simulation. This will allow us subsequently to compute the loss distribution of the bond portfolio resulting from credit events.

The description given above provides the basic intuition behind the use of Monte Carlo simulation for computing the credit loss distribution. In the context of its intended use here, the Monte Carlo simulation technique can be described as a computational scheme that utilizes sequences of random numbers generated from a given probability distribution function to derive the distribution of portfolio credit loss. The distribution of portfolio credit loss can be computed both under the default mode, which only considers whether the obligor is solvent or not, and under the migration mode that includes credit events arising from rating changes. Consequently, to compute the credit loss under the default mode, we only need to consider the loss resulting from obligor default; whereas under the migration mode, we have to compute the credit loss associated with rating migrations in addition to the credit loss resulting from obligor default.

To generate the credit loss for one run of the Monte Carlo simulation, we need to go

through three computational steps described below.

1. Simulate correlated random numbers that model the joint distribution of asset returns of the obligors in the portfolio.
2. Infer the implied credit rating of each obligor based on simulated asset returns.
3. Compute the potential loss in value based on the implied credit rating, and in those cases where the asset return value signals an obligor default, compute a random loss on default value by sampling from a beta distribution function.

Repeating the above simulation run many times and computing the credit loss under each simulation run will allow us to generate the distribution of portfolio credit loss under the migration mode. If we are only interested in the credit loss distribution under the default mode, we can compute this by setting credit loss associated with rating migrations to zero in the simulation run. In the following sections we will briefly describe the computational steps that are required to generate the credit loss distribution.

Generating Correlated Asset Returns

We briefly described earlier the steps involved in simulating the credit loss distribution for a bond portfolio. As the first step, we mentioned that correlated random numbers that model the joint distribution of asset returns have to be simulated. An immediate question that will arise in our minds is whether the obligor-specific means and standard deviations of asset returns have to be taken into account in the simulations. The simple answer to this question is no. This is because the simulated asset returns will be compared against the rating migration thresholds, which are computed under the assumption that asset returns are standardized normal random variables. As a result, the obligor-specific mean and standard deviation of asset returns are not required for

simulating the loss distribution. Hence, we will assume that obligor asset returns are standard normal random variables (having mean zero and standard deviation equal to one). Under this assumption, the Monte Carlo simulation method will require generating a sequence of random vectors that are sampled from a standardized multivariate normal distribution.

Many standard numerical packages provide routines to generate sequences of random vectors sampled from a multivariate normal distribution. Although the details of the implementation are not discussed here, we will briefly outline the numerical procedure commonly used to generate sequences of multivariate normal random vectors. Let us assume that the multivariate normal random vector has a mean vector \vec{a} and covariance matrix C . Covariance matrices have the property that they are symmetric and positive definite (meaning all its eigenvalues are greater than zero). Given such a matrix, it is possible to find a unique lower triangular matrix L such that,

$$L L^T = C \quad (1)$$

The matrix L is referred to as the Cholesky factor corresponding to the positive definite matrix C . Once the Cholesky factor is determined, generating a sequence of random vectors with the desired multivariate distribution only requires generating a sequence of independent standard normal random variables. If \vec{x} denotes the vector of independent standard normal random variables, the vector \vec{r} with the desired multivariate normal distribution can be constructed as follows:

$$\vec{r} = \vec{a} + L \vec{x} \quad (2)$$

The sequence of random vectors \vec{r} that are generated will have the property that their joint distribution is multinormal with mean vector \vec{a} and covariance matrix C .

It is useful to note here that by setting the mean vector \vec{a} to zero and the covariance matrix equal to the correlation matrix, we can generate a sequence of random vectors whose

Table 1 Rating Transition Probabilities and z-Thresholds

Transition to Rating	Transition Probabilities		z-Threshold (Gaussian)		z-Threshold (Student's <i>t</i>)	
	A2-rated	A3-rated	A2-rated	A3-rated	A2-rated	A3-rated
Aaa	0.05	0.05	3.28	3.28	5.04	5.04
Aa1	0.06	0.11	3.05	2.95	4.43	4.15
Aa2	0.30	0.05	2.64	2.86	3.49	3.96
Aa3	0.80	0.24	2.25	2.61	2.77	3.43
A1	5.57	1.55	1.49	2.05	1.66	2.45
A2	80.75	8.68	-1.15	1.24	-1.24	1.35
A3	7.48	75.40	-1.65	-1.08	-1.86	-1.16
Baa1	2.99	7.03	-2.05	-1.48	-2.45	-1.65
Baa2	0.83	3.83	-2.27	-1.87	-2.79	-2.18
Baa3	0.41	1.50	-2.43	-2.15	-3.08	-2.61
Ba1	0.29	0.57	-2.60	-2.33	-3.40	-2.90
Ba2	0.11	0.20	-2.69	-2.41	-3.58	-3.05
Ba3	0.12	0.23	-2.81	-2.54	-3.86	-3.28
B1	0.03	0.35	-2.86	-2.85	-3.96	-3.96
B2	0.07	0.05	-2.98	-2.94	-4.25	-4.15
B2	0.03	0.05	-3.06	-3.06	-4.43	-4.43
Caa-C	0.03	0.01	-3.16	-3.09	-4.67	-4.50
Default	0.08	0.10	-1000	-1000	-1000	-1000

joint distribution is standardized multivariate normal. Since the joint distribution of obligor asset returns was assumed to be standardized multivariate normal, this sequence of random vectors will be the one of interest to us.

Inferring Implied Credit Rating

The next step in the credit loss simulation process is to infer the credit rating of the various obligors in the portfolio as implied by the simulated asset return vector. In order to do this, we need to determine the thresholds against which the asset returns will be compared to identify rating changes or obligor default. To illustrate how these thresholds can be determined, let us consider an obligor that has a current credit rating of A1. (Moody's rating categories are used here to denote the credit rating of an obligor.) Let $p_{A1, Aaa}$ denote the probability of transitioning to the credit rating Aaa. Under the assumption that the asset returns of the obligor are normally distributed, the credit event that signals the obligor rating migration from A1 to Aaa will occur when the standardized asset returns of the obligor exceed the threshold $z_{A1, Aaa}$. This

threshold can be determined by solving the following integral equation:

$$p_{A1, Aaa} = \frac{1}{\sqrt{2\pi}} \int_{z_{A1, Aaa}}^{\infty} \exp\left(-\frac{1}{2} x^2\right) dx \quad (3)$$

A rating transition of this obligor from A1 to Aa1 will occur if the asset return falls between the thresholds $z_{A1, Aaa}$ and $z_{A1, Aa1}$. The threshold $z_{A1, Aa1}$ can be determined by solving the following integral equation:

$$p_{A1, Aa1} = \frac{1}{\sqrt{2\pi}} \int_{z_{A1, Aa1}}^{z_{A1, Aaa}} \exp\left(-\frac{1}{2} x^2\right) dx \quad (4)$$

One can extend this sequential rule to determine the thresholds for migrating to other rating grades. We note here that these z-thresholds are a function of the current credit rating of the obligor. Table 1 shows the rating transition probabilities and the corresponding z-thresholds for two different obligor credit ratings when the asset returns are assumed to be Gaussian (normal distribution).

Let us consider the two-bond portfolio given in Table 2 to illustrate the specific steps involved

Table 2 Security Level Details for the Two-Bond Portfolio

Description	Bond 1	Bond 2
Issuer rating grade	A3	A2
Dirty price for \$1 nominal	1.0533	1.0029
Nominal exposure	\$1,000,000	\$1,000,000
Modified duration	4.021	3.747
Convexity	19.75	16.45
Mean recovery rate	35%	35%
Volatility of recovery rate	25%	25%

in computing the credit loss from one simulation run for this portfolio. Suppose during one draw from a bivariate normal distribution the random asset returns are, respectively, 2.5 for bond 1 and -3.5 for bond 2. Given the initial issuer rating of A3 for bond 1, one can infer from the z -threshold values for A3-rated issuers in Table 1 that an asset return value of 2.5 implies a credit rating change of the issuer to an A1 rating. Similarly, one can infer from Table 1 that an asset return value of -3.5 for an A2-rated issuer will imply that the issuer defaults on the outstanding debt. Proceeding in this manner, the implied credit rating of the debt issuers in the two-bond portfolio for every simulation run can be derived on the basis of the z -threshold values in Table 1.

For a general n -bond portfolio, the implied credit rating of the debt issuers for each simulation run can be similarly determined. It is important to note here that the number of obligors in an n -bond portfolio will be less than or equal to n . In the case where there are fewer than n obligors, credit rating changes should be identical for all bonds issued by the same obligor in any simulation run. This has the implication that the dimension of the simulated asset return vector should be equal to the number of obligors or debt issuers in the bond portfolio.

Computing Credit Loss

Once the implied rating changes for the obligors are determined for the simulated asset re-

turn vector, the corresponding credit loss associated with such implied rating changes could be determined. It is important to note here that we generically refer to the price change resulting from the rating change as a loss although a credit improvement of the obligor will result in a price appreciation for the bond. The price change of a bond as a result of a rating change for the bond issuer will be a function of the change in the yield spreads and the maturity of the bond. Assuming that our interest is to estimate the credit loss due to a change in the bond's mark to market value as a result of the rating change, we would want to know at what time horizon the bond's price has to be marked to market. If we were to compute the worst-case loss scenario, it would correspond to a rating change of the obligor during the next trading day. In this case, the current trading price of the bond and its risk parameters, duration, and convexity serve to characterize the credit loss. The credit loss resulting from a rating change from the i th grade to the k th grade will be a function of the change in the bond yield and is given by,

$$\Delta P_{ik} = P_{dirty} \times D \times \Delta y_{ik} - 0.5 \times P_{dirty} \times C \times \Delta y_{ik}^2 \quad (5)$$

In equation (5), P_{dirty} is the dirty price of the bond (accrued interest plus traded price), Δy_{ik} is the yield change when issuer rating changes from grade i to grade k , D is the modified duration of the bond, and C the convexity. When the issuer migrates to the default state, the credit loss will be equal to the dirty price P_{dirty} minus the recovery rate.

To illustrate the credit loss computation, let us again focus on the two-bond portfolio example. In this example, the asset return value signaled an upgrade to an A1 rating from the current rating of A3 for bond 1. Suppose the change in the yield spread associated with this rating change is -30 basis points. Then, substituting the various parameter values into equation (5), the credit loss for \$1 million notional amount

held of bond 1 is given by,

$$\begin{aligned} \text{Credit loss} &= 1,000,000 \times [1.0533 \times 4.021 \\ &\quad \times (-0.003) - 0.5 \times 1.0533 \times 19.75 \\ &\quad \times (-0.003)^2] = -\$12,799.6 \end{aligned}$$

We note here that the negative sign associated with the credit loss is suggesting that this rating change results in a profit rather than a loss.

For bond 2, the simulated asset return value of -3.5 implies default of the obligor. In this case, we must find a random loss on default, which will be a function of the assumed recovery rate distribution. Many credit risk models assume the recovery rate process to have a beta distribution with mean μ and standard deviation σ . Given the values for μ and σ , the parameters α and β that define the beta distribution with the desired mean and standard deviation can be computed as given below:

$$\alpha = \frac{\mu^2(1-\mu)}{\sigma^2} - \mu \quad (6)$$

$$\beta = \frac{\alpha}{\mu} - \alpha \quad (7)$$

For the bond in question, let us assume the mean recovery rate to be $\mu = 35\%$ and the standard deviation of the recovery rate to be $\sigma = 25\%$. Corresponding to these recovery rate values, the parameters of the beta distribution function are $\alpha = 0.924$ and $\beta = 1.716$.

The random recovery rate for bond 2 for the simulation run is determined by drawing a random number from a beta distribution with α and β parameter values as above. Let us assume that the simulated recovery value is 40% for bond 2. The implied loss on default for the bond that trades at a dirty price of \$1.0533 is then equal to 0.6533 (bond dirty price minus the recovery value). The credit loss arising from bond 2 for this simulation run will be equal to the nominal exposure times the loss on default, which is equal to \$653,300.

For the two-bond portfolio, the total credit loss for this simulation run is the sum of the two losses. If this simulation run corresponds to the i th run, the portfolio credit loss under the

i th simulation run, denoted ℓ_i , is given by,

$$\ell_i = -\$12,799.6 + \$653,300 = \$640,500.4$$

It is important to emphasize here that for a general n -bond portfolio, all bonds of a particular issuer should have the same recovery value for any one simulation run if they have the same seniority. This information must be taken into account when simulating the credit loss distribution of a general n -bond portfolio.

Computing Expected and Unexpected Loss

The above procedure outlined how the portfolio credit loss can be computed for one simulation run. By repeating the simulation run N times where N is sufficiently large, the distribution of the credit losses can be generated. Given the simulated loss distribution, one can compute various risk measures of interest. For instance, the expected and unexpected credit loss (the first two moments of the loss distribution) using the simulated loss data can be computed as follows:

$$EL_P = \frac{1}{N} \sum_{i=1}^N \ell_i \quad (8)$$

$$UL_P = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (\ell_i - EL_P)^2} \quad (9)$$

To reduce the standard error of the estimated portfolio expected loss, it is common practice to perform antithetic sampling when performing the Monte Carlo simulation. The idea behind antithetic sampling technique is that when random samples are drawn from a symmetric distribution, sampling errors can be avoided if the antithetic or symmetric part of the random sample is also drawn. This will ensure that the empirical mean of the random samples is equal to the mean of the distribution function from which the samples are drawn. Including the antithetic part of the samples will double the total number of simulation runs.

Importance Sampling

The Monte Carlo simulation technique described so far is based on random sampling. In such a sampling process, the probability of any value being generated is proportional to the probability density at that point. This property will have the effect of generating asset return values in the simulations that tend to cluster around the mean of the normal distribution function. Rating migrations and obligor defaults, however, are events that are driven by asset return values that deviate significantly from the mean of the normal distribution. The implication is that a significant proportion of the simulation runs will not trigger any credit events. If our intention is to compute the expected and unexpected loss of the portfolio from the simulations, random sampling will be the appropriate method to use. If, on the other hand, we expect to compute risk measures associated with tail events from the simulated data, random sampling will be inefficient.

If our primary intention of performing Monte Carlo simulations is to compute tail risk measures (to be discussed in the next section), we can improve the simulation efficiency through importance sampling (see Glasserman and Li, 2005). Simulation efficiency in our context refers to the number of simulation runs required to compute the risk measure of interest for a specified standard error of the estimate. Importance sampling artificially inflates the probability of choosing random samples from those regions of the distribution that are of most interest to us. This would mean that our sampling process is biased in such a manner that a large number of credit events are simulated relative to what would occur in practice. In the Monte Carlo simulation terminology, the adjustment made to the probability of a particular point being sampled is referred to as its importance weight. To estimate the true probability distribution of the simulated losses when performing importance sampling, we have to restore the actual probability of each sample by multiplying it by the inverse of its importance weight. In

practice, when the number of obligors in the portfolio is large (this is usually true for the benchmark portfolio), performing importance sampling will lead to improved computational efficiency.

Tail Risk Measures

The discussions so far focused on how the mean (expected loss) and standard deviation (unexpected loss) of the credit loss distribution for a corporate bond portfolio can be computed from the simulations. If the distribution of credit losses is normally distributed, standard deviation can be interpreted as the maximum deviation around the mean that will not be exceeded with a 66% level of confidence. Since the credit loss distribution is not normal, a similar interpretation to the standard deviation of credit loss does not hold. In most cases, computing the probability of incurring a large credit loss on a corporate bond portfolio using unexpected loss information is usually not possible.

In general, a major preoccupation of most corporate bond portfolio managers is to structure the portfolio so as to minimize the probability of large losses. To do this an estimate of the potential downside risk of the portfolio becomes a key requirement. Computing any downside risk measure requires an estimate of the probability mass associated with the tail of the loss distribution. If the simulated credit loss distribution is available, it is quite easy to derive appropriate tail risk measures of interest. For a corporate bond portfolio, the tail risk measures of interest are credit value at risk and expected shortfall risk. Both these risk measures are discussed below, and the method to compute these measures using the simulated loss distribution is also indicated.

Credit Value at Risk

Credit value at risk (CVaR) is a tail risk measure that quantifies the extreme losses arising from credit events that can occur at a prespecified

level of confidence over a given time horizon. In practical terms, CVaR provides an estimate of the maximum credit loss on a portfolio, which could be exceeded by a probability p . Without loss of generality, it will be assumed that this probability is expressed in percentage. If the probability p is chosen to be sufficiently small, one can expect that the credit loss will not exceed the CVaR amount at a high confidence level given by $(100 - p)\%$. Stated differently, CVaR at a confidence level of $(100 - p)\%$ refers to the maximum dollar value of loss that will only be exceeded $p\%$ of the time over the given time horizon. Since losses from credit risk are measured over a one-year horizon, the CVaR measure we will compute also relates to a one-year time horizon.

In order to compute CVaR to quantify the tail risk of the credit loss distribution in a corporate bond portfolio, we need to specify the confidence level at which it should be determined. Within the framework of economic capital allocation, CVaR is usually measured at a confidence level that reflects the solvency standard of the institution in question. For instance, the solvency standard of an AA-rated institution is typically 99.97%, and hence, CVaR will be computed at this confidence level. From a portfolio management perspective, however, the confidence level of interest for CVaR estimate would typically be much lower. The motivation for this is that portfolio managers have to provide monthly performance reports to clients, and return deviations over this period need to be explained. In this case, estimating CVaR at a confidence level of 91.6% would imply that the underperformance relative to the benchmark will exceed the monthly CVaR estimate once during the year on average if monthly performance reporting is used. In this case, the CVaR estimate provides useful information to the portfolio manager and the client in terms of both the return surprises one could expect and also to actually observe it happen.

Motivated by the above observation, we will choose the confidence level for the CVaR esti-

mate to be 90%. At this level of confidence, the portfolio manager can expect the credit losses to exceed the monthly CVaR estimate for one reporting period during the year. Once the confidence level for CVaR is specified, estimating CVaR from the simulated loss distribution is quite simple. If, for instance, the number of simulation runs is equal to 10,000, then the 90% CVaR will be equal to the 1,000th worst-case credit loss. Assuming that the simulated credit losses are sorted in an ascending order of magnitude, the credit loss corresponding to the 9,000th row in the sorted data will be the CVaR at 90% confidence level for 10,000 simulation runs.

Considering that standard practice in portfolio management is to report risk measures relative to the current market value of the portfolio, we will introduce the term “percentage credit value at risk.” If M_p denotes the current market value of the portfolio, the percentage CVaR at 90% confidence level is defined as,

$$\%CVaR_{90\%} = \frac{CVaR_{90\%}}{M_p} \quad (10)$$

Expected Shortfall

Although CVaR is a useful tail risk measure, it fails to reflect the severity of loss in the worst-case scenarios in which the loss exceeds CVaR. In other words, CVaR fails to provide insight as to how far the tail of the loss distribution extends. This information is critical if the portfolio manager is interested in restricting the severity of the losses in the worst-case scenarios under which losses exceed CVaR. In order to better motivate this point, Figure 1 shows the credit loss distribution for two portfolios that have identical CVaR at the 90% level of confidence.

Examining Figure 1 it is clear that although both portfolios have identical CVaR at the 90% confidence level, the severity of the worst-case losses that exceed the 90% confidence level are lower for portfolio 1 compared to portfolio 2. This example suggests that in order to

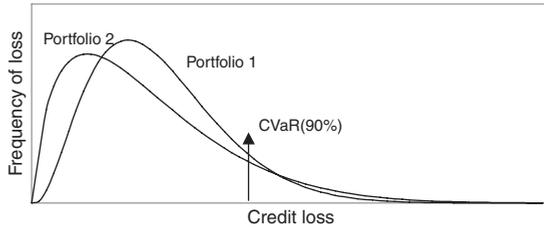

Figure 1 Credit Loss Distribution for Two Portfolios

investigate whether portfolio credit risk is well diversified, it is not sufficient if we only examine the tail probability beyond some confidence level. Examining the loss exceedence beyond the desired confidence level at which CVaR is estimated is important to gauge the loss severity in the tail part of the loss distribution.

One such risk measure that provides an estimate of the loss severity in the tail part of the loss distribution is the *expected shortfall* (ES), which is sometimes also referred to as conditional VaR. Similar to CVaR, expected shortfall requires specifying a confidence level and a time horizon. Considering that ES is usually used in conjunction with CVaR, the confidence level should be chosen as 90% and the time horizon one year. A simple interpretation of ES is that it measures the average loss in the worst $p\%$ scenarios where $(100 - p)\%$ denotes the confidence level at which CVaR is estimated. In mathematical terms, expected shortfall can be defined as the conditional expectation of that part of the credit loss that exceeds the CVaR limit. The interpretation of ES as conditional VaR follows from this definition. If $\tilde{\ell}$ denotes the loss variable, ES can be defined as given below:

$$ES = E[\tilde{\ell} \mid \tilde{\ell} > CVaR] \quad (11)$$

Given the simulated loss distribution of the portfolio, computing expected shortfall risk is quite simple. Let ℓ_i denote the simulated credit loss distribution for the i th simulation run, and let us assume that the losses are sorted in ascending order. If the number of simulation runs is equal to N , the relevant equation to compute

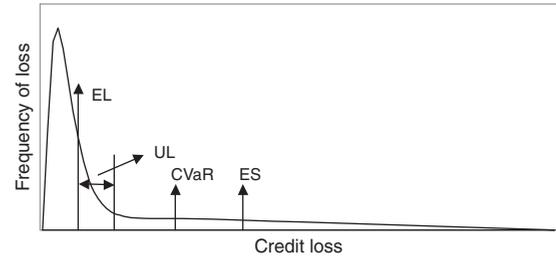

Figure 2 Various Risk Measures for Portfolio Credit Risk

ES at the 90% confidence level from the simulations is given below:

$$ES_{90\%} = \frac{1}{(1 - 0.9)N} \times \sum_{i=0.9N+1}^N \ell_i \quad (12)$$

The percentage ES at 90% confidence level is defined as,

$$\%ES_{90\%} = \frac{ES_{90\%}}{M_p} \quad (13)$$

Figure 2 shows the various credit risk measures presented here that can be computed from the simulated loss data.

Relaxing the Normal Distribution Assumption

A growing body of empirical studies conducted on financial time series data suggests that returns on traded financial instruments exhibit volatility clustering and extreme movements that are not representative of a normally distributed random variable. Another commonly observed property of financial time series is that during times of large market moves, there is greater degree of comovement of returns across many firms compared to those observed during normal market conditions. This property, usually referred to as tail dependence, captures the extent to which the dependence (or correlation) between random variables arises from extreme observations. Stated differently, for a given level of correlation between the random variables a multivariate distribution with tail dependence has a much greater tendency to generate

simultaneous extreme values for the random variables in contrast to those distributions that do not have this property.

A multivariate normal distribution does not exhibit tail dependence. The dependence or correlation structure exhibited between the random variables in a multivariate normal distribution arises primarily from comovements of the variables around the center of the distribution. As a consequence, contagion or herding behavior commonly observed in financial markets is difficult to model within the framework of multivariate normal distributions. In order to capture contagion and herding behavior in financial markets, distributions that exhibit tail dependence should be used to model financial variables of interest. In the context of credit risk modeling, contagion effects would result in greater comovement of asset returns across firms during periods of recession leading to higher probability of joint defaults. If we model the joint distribution of asset returns to be multivariate normal, we will fail to capture the effects of contagion in the aggregate portfolio credit risk measures we compute. In the next section we relax the assumption that the distribution of asset returns is multivariate normal.

Student's t Distribution

Among the class of distribution functions that exhibit tail dependence, the family of multivariate normal mixture distributions, which include *Student's t distribution* and generalized hyperbolic distribution, is an interesting alternative. This is because normal mixture distributions inherit the correlation matrix of the multivariate normal distribution. Hence, correlation matrices for normal mixture distributions are easy to calibrate.

Formally, a member of the m -dimensional family of variance mixtures of normal distributions is equal in distribution to the product of a scalar random variable s and a normal random

vector \vec{u} having zero mean and covariance matrix Σ . The scalar random variable s is assumed to be positive with finite second moment and independent of \vec{u} . If \vec{x} denotes a random vector having a multivariate normal mixture distribution, our definition leads to the following equation:

$$\vec{x} = s \cdot \vec{u} \quad (14)$$

Since normal mixture distributions inherit the correlation matrix of the multivariate normal distribution, we have the following relationship:

$$\text{Corr}(x_i, x_k) = \text{Corr}(u_i, u_k) \quad (15)$$

The random vector \vec{x} will have multivariate t distribution with ν degrees of freedom if the scalar random variable s is defined as below:

$$s = \sqrt{\frac{\nu}{\omega}} \quad (16)$$

In equation (16), ω is a chi-square distributed random variable with ν degrees of freedom. For $\nu > 2$, the resulting Student's t distribution will have zero mean vector and covariance matrix $\frac{\nu}{\nu-2}\Sigma$. The Student's t distribution has the property that as ν increases, the distribution approaches a normal distribution. In fact, for values of ν greater than 25, it is difficult to distinguish between a normal distribution and t distribution. In a multivariate setting, as ν decreases, the degree of tail dependence between the random variables will increase. For financial time series, ν is typically around 4 (Platen and Sidorowicz, 2007).

An important distinction between the t distribution and the normal distribution is that uncorrelated random variables are mutually independent, whereas the components of multivariate t are in general dependent even if they are uncorrelated. In modeling credit risk, this property makes it possible to capture comovements of asset returns between firms in extreme market situations even if the asset returns exhibit little or no correlation under normal market conditions.

In the univariate case, the probability density function of the Student's t distribution with ν degrees of freedom has the following functional form:

$$f_\nu(x) = \frac{\Gamma((\nu + 1)/2)}{\sqrt{\nu\pi} \times \Gamma(\nu/2)} \times \left(1 + \frac{x^2}{\nu}\right)^{-(\nu+1)/2} \quad (17)$$

In equation (17) $\Gamma(\cdot)$ is the gamma function, which is given by

$$\Gamma(\alpha) = \int_0^\infty x^{\alpha-1} e^{-x} dx \quad (18)$$

Loss Simulation Under Multivariate t Distribution

The steps involved in simulating the credit loss distribution when asset returns are multivariate t follow the same procedure as for the multivariate normal case. Instead of generating the sequence of correlated asset returns from a multivariate normal distribution, we now have to generate this sequence from a multivariate t distribution. The next step will involve inferring the credit rating change of the various obligors in the portfolio as implied by the simulated asset return vector. To do this, we need to determine the thresholds against which the asset returns will be compared to identify rating changes or obligor default. These z -thresholds have to be calibrated to correspond to the Student's t distribution. Specifically, the integrand for computing the z -thresholds will be the Student's t density function.

For purpose of illustration, let us consider an obligor that has a current credit rating of A1. Let $p_{A1,Aaa}$ denote the probability of transitioning to the credit rating Aaa. Under the assumption that the asset returns of the obligor are t -distributed, the credit event that signals the obligor rating migration from A1 to Aaa will occur when the asset returns of the obligor exceed the threshold $z_{A1,Aaa}$. This threshold can be determined by solving the following integral

equation:

$$p_{A1,Aaa} = \frac{\Gamma((\nu + 1)/2)}{\sqrt{\nu\pi} \times \Gamma(\nu/2)} \int_{z_{A1,Aaa}}^\infty \left(1 + \frac{x^2}{\nu}\right)^{-(\nu+1)/2} dx \quad (19)$$

A rating transition of this obligor from A1 to Aa1 will occur if the asset return falls between the thresholds $z_{A1,Aaa}$ and $z_{A1,Aa1}$. The threshold $z_{A1,Aa1}$ can be determined by solving the following integral equation:

$$p_{A1,Aa1} = \frac{\Gamma((\nu+1)/2)}{\sqrt{\nu\pi} \times \Gamma(\nu/2)} \int_{z_{A1,Aa1}}^{z_{A1,Aaa}} \left(1 + \frac{x^2}{\nu}\right)^{-(\nu+1)/2} dx \quad (20)$$

One can extend this sequential rule to determine the thresholds for migrating to other rating grades. Table 1 shows the z -threshold values computed using the rating transition probabilities for A2- and A3-rated obligors when the asset returns are t -distributed.

The rest of this section discusses the procedure to generate a sequence of random vectors from a multivariate t distribution. Following the discussion earlier in this entry, a random vector with multivariate t distribution having ν degrees of freedom can be derived by combining a chi-square random variable with ν degrees of freedom and a random vector that is normally distributed and independent of the chi-square random variable. This procedure will allow us to generate a sequence of multivariate t -distributed random vectors with ν degrees of freedom.

To generate a sequence of chi-square distributed random variables, the standard procedure is to make use of the relationship between chi-square distribution and gamma distribution. A random variable x is said to have gamma distribution if its density function is defined as below:

$$f(x) = \begin{cases} \frac{1}{\Gamma(\alpha)\beta^\alpha} x^{\alpha-1} e^{-x/\beta}, & x > 0 \\ 0, & x \leq 0 \end{cases} \quad (21)$$

In equation (21) $\alpha > 0$ and $\beta > 0$ are the parameters of the gamma distribution, and $\Gamma(\alpha)$

is the gamma function given by equation (18). The chi-square distribution with ν degrees of freedom is a special case of the gamma distribution with parameter values $\alpha = \nu/2$ and $\beta = 2$.

Given the above relationship between gamma and chi-square distribution, a sequence of random variables having chi-square distribution with ν degrees of freedom can be generated by sampling from a gamma distribution with parameter values $\alpha = \nu/2$ and $\beta = 2$. Most standard software packages provide routines to generate random sequences from a gamma distribution. Hence, we will not discuss the details concerned with generating such a sequence of random variables.

To summarize, the following are the steps involved in generating an n -dimensional sequence of multivariate t distributed random variables with ν degrees of freedom.

Step 1: Compute the Cholesky factor L of the matrix C where C is the $n \times n$ asset return correlation matrix.

Step 2: Simulate n independent standard normal random variates z_1, z_2, \dots, z_n and set $\tilde{u} = L\tilde{z}$.

Step 3: Simulate a random variate ω from chi-square distribution with ν degrees of freedom that is independent of the normal random variates and set $s = \frac{\sqrt{\nu}}{\sqrt{\omega}}$.

Step 4: Set $\tilde{x} = s \cdot \tilde{u}$ which represents the desired n -dimensional t variate with ν degrees of freedom and correlation matrix C .

Repeating the steps 2 to 4 will allow us to generate the sequence of multivariate t -distributed random variables.

Computing the credit loss for the two-bond portfolio in Table 2 will require comparing the asset return values under each simulation run against the z -thresholds given in Table 1 to trigger rating migrations and defaults for the obligors in the two-bond portfolio. On the basis of the implied rating changes assigned to the obligors

using simulated asset returns, the credit loss for each simulation run can be calculated. The rest of the steps involved in computing the credit risk measures of interest from the simulated loss distribution are identical to the ones for the normal distribution case.

KEY POINTS

- Monte Carlo methods provide a flexible tool to simulate credit loss distribution and are relatively simple to implement.
- To simulate the credit loss distribution under the rating migration mode, rating transition probabilities have to be transformed into corresponding z -thresholds for the assumed distribution function for the asset returns.
- Simulating multivariate t random vectors requires appropriately scaling the sequence of multivariate normal vectors by another sequence of chi-square random variables that are uncorrelated with the normal random vectors.
- From the simulated loss distribution, various tail risk measures of interest can be computed.
- Using techniques such as importance sampling can significantly reduce the standard errors of tail risk measures for a given number of simulation runs.

Managing Credit Spread Risk Using Duration Times Spread (DTS)

ARIK BEN DOR, PhD

Managing Director, Barclays

LEV DYNKIN, PhD

Managing Director, Barclays

JAY HYMAN, PhD

Managing Director, Barclays, Tel Aviv

Abstract: Extensive empirical research has shown that the spread volatility of credit securities is linearly proportional to their level of spread. This finding holds true across corporate and sovereign issuers, for both cash and credit default swaps. A superior measure of spread risk for credit securities is the product of spread duration and spread, a measure referred to as duration times spread (DTS). DTS measures the sensitivity of the price of a bond to relative changes in spread, which are much more stable through time and cross-sectionally than absolute spread volatilities. DTS allows for better risk projection, hedging, replication, and portfolio construction.

The traditional presentation of the asset allocation in a portfolio or a benchmark is in terms of percentage of market value. For fixed-income portfolios, it is widely recognized that this is not sufficient, as differences in durations can cause two portfolios with the same market weight allocations to have very different exposures to macro-level risks. Market practices have evolved to address this issue. A common approach to structuring a fixed-income portfolio or comparing it to a benchmark is to partition it into homogeneous market cells comprised of securities with similar characteristics. Many fixed-income portfolio managers have become

accustomed to expressing their cell allocations in terms of contributions to duration—the product of the percentage of portfolio market value in a given market cell and the average duration of securities comprising that cell. This represents the sensitivity of the portfolio to a parallel shift in yields across all securities within this market cell. For credit portfolios, the corresponding measure would be contributions to spread duration, measuring the sensitivity to a parallel shift in spreads. Determining the set of active spread duration bets to different market cells and issuers is one of the primary decisions made by credit portfolio managers.

Yet all spread durations were not created equal. Just as one could create a portfolio that matches the benchmark exactly by market weights, but clearly takes more *credit risk* (e.g., by investing in the longest duration credits within each cell), one could match the benchmark exactly by spread duration contributions and still take more credit risk—by choosing the securities with the widest spreads within each cell. These bonds presumably trade wider than their peer groups for a reason—that is, the market consensus has determined that they are more risky—and they are often referred to as high beta, because their spreads tend to react more strongly than the rest of the market to a systematic shock. We found strong empirical evidence that this relation takes on a nearly perfect linear form: Spread changes are linearly proportional to spread levels at the start of the period.

Based on the linear relation between spread level and the volatility of spread changes, we have advocated since 2005 a new measure of risk sensitivity that utilizes spreads as a fundamental part of the credit portfolio management process. To reflect the view that higher spread credits represent greater exposures to sector-specific risks, we represent sector exposures by contributions to *duration times spread (DTS)*, computed as the product of market weight, spread duration, and spread. For example, an overweight of 5% to a market cell implemented by purchasing bonds with a spread of 80 basis points (bps) and spread duration of three years would be equivalent to an overweight of 3% using bonds with an average spread of 50 bps and spread duration of eight years.

The shift from spread duration exposures to DTS exposures as the measure of market risk sensitivity embraces a different paradigm for credit spread movement—in the form of relative spread changes rather than parallel shifts in spread. The introduction of the DTS paradigm was motivated by an extensive empirical study using over 560,000 monthly observations of individual corporate bonds spreads, spanning the

period of September 1989 to January 2005.¹ The analysis showed that changes in spreads are not parallel, but rather depend on the level of spread. Specifically, spread change volatility (both systematic and idiosyncratic) was shown to be linearly proportional to spread level for both investment-grade and high-yield credit securities, irrespective of the sector, duration, or time period. Subsequent studies indicated that the results were not confined to the realm of U.S. corporate bonds, but also extend to other spread asset classes with a significant default risk such as credit default swaps, European corporate and sovereign bonds, and emerging market sovereign debt denominated in U.S. dollars.² Furthermore, even from a theoretical standpoint structural credit risk models such as Merton (1974) imply a near-linear relation between spread level and volatility.³

The DTS concept has many implications for portfolio managers, both in terms of the way they manage exposures to industry and credit quality factors (systematic risk) and in terms of their approach to issuer exposures (nonsystematic risk). After a short review of the DTS concept and the empirical evidence supporting it, we discuss how it can help investors improve projected risk estimates, hedging, replication, and portfolio construction.

THE DTS CONCEPT

To understand the intuition behind DTS, consider the return, R_{spread} , due strictly to change in spread. Let D denote the spread duration of a bond and s its spread; the spread change return is then:

$$R_{\text{spread}} = -D \cdot \Delta s \quad (1)$$

Or, equivalently,

$$R_{\text{spread}} = -D \cdot s \cdot \frac{\Delta s}{s} \quad (2)$$

That is, just as spread duration is the sensitivity to an absolute change in spread (e.g., spreads widen by 5 bps), DTS ($D \cdot s$) is the sensitivity to a relative change in spread (e.g., spreads widen

by 5%). Note that this notion of relative spread change provides for a formal expression of the idea mentioned earlier—that credits with wider spreads are riskier since they tend to experience greater spread changes.

In the absolute spread change approach shown in equation (1), we can see that the volatility of excess returns can be approximated by

$$\sigma_{\text{return}} \cong D \cdot \sigma_{\text{spread}}^{\text{absolute}} \quad (3)$$

while in the relative spread change approach of equation (2), excess return volatility follows

$$\sigma_{\text{return}} \cong D \cdot s \cdot \sigma_{\text{spread}}^{\text{relative}} \quad (4)$$

Given that the two representations above are equivalent, why should one of them be preferable to another? The key advantage of modeling changes in spreads in relative terms is the resulting stability. The above equations, for simplicity, present returns and volatilities as idealized concepts. We have not added subscripts to specify whether we are referring to specific securities or sectors, or over what time period. Yet the way spread changes of different securities relate to each other, or the way volatilities in one time period relate to those in another, can be of critical importance in measuring and controlling portfolio risk.

For example, to determine a portfolio's exposure to a systematic widening of spreads, one needs to know how spread changes are likely to be realized across a sector. If one is concerned that spreads might move in parallel, then exposures should be measured as the overall contribution to spread duration as per equation (1). However, if spreads tend to change proportionally, then the contribution to DTS provides the correct exposure to such an event.

Similarly, volatility can be measured or projected in many different ways. Historically realized volatilities can be measured using observed spread changes at a specified frequency over a given sample period. Projections of forward-looking volatilities are the key building blocks of risk management systems. The accuracy with which historically re-

alized volatilities can project future volatilities is therefore of fundamental importance. If relative spread volatilities can be predicted with greater accuracy than absolute spread volatilities, then equation (4) should be preferred over (3). We found this to be the case, based on extensive empirical evidence from credit markets.

DTS AS BETA-ADJUSTED SPREAD DURATION

What are the dynamics of credit spread changes? Do spreads tend to widen in parallel, or do wider spreads widen by more? Figure 1 shows a specific example in which spread changes show a clear dependence on spread. The figure shows the changes in spreads experienced by key issuers in the Communications sector of the Barclays Capital Corporate Index in January 2001, during a temporary rally in the midst of the dot-com crisis. It is clear that this sector-wide rally was not characterized by a purely parallel shift; rather, issuers with wider spreads tightened by more.

Certainly, not all spread changes follow such a clear pattern. In many months, there are no large industry-wide spread changes, and spread changes are mostly idiosyncratic in nature. Occasionally, an industry will experience a systematic spread change that does seem to take the form of a parallel shift. However, an extensive set of regressions using individual bond spread changes across eight distinct market sectors and 185 months indicated that systematic factors expressed in terms of relative spread changes across an industry were able to capture nearly twice as much of the overall spread variance as factors based on parallel shifts in industry spreads. Furthermore, Ben Dor et al. (2007) found clear evidence that whenever a systematic widening or tightening of spreads across an industry occurred, credits with the highest spreads at the beginning of the month were most likely to experience the largest change in spreads.

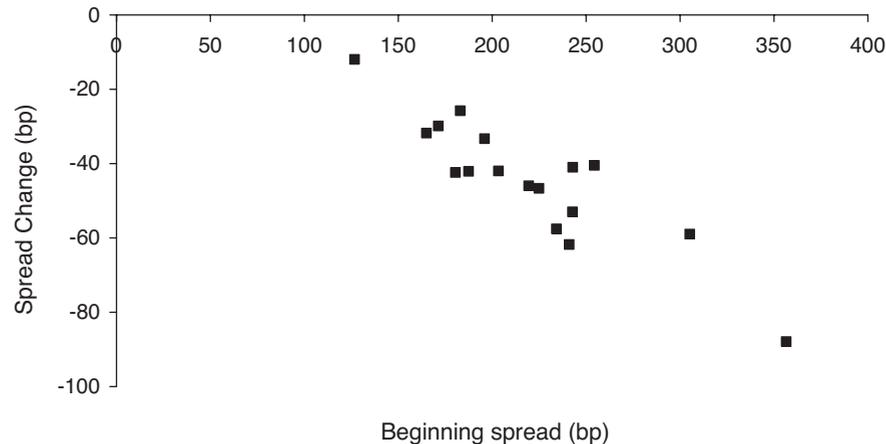

Figure 1 Average Spreads and Spread Changes for Key Issuers in the Communications Sector of the Barclays Capital Corporate Index (January 2001)
Source: Barclays Capital.

This idea may strike investors as reminiscent of the idea of “market beta” that is familiar from the capital asset pricing model (CAPM), in which the beta of a given security represents the extent to which it would be expected to participate in a market-wide rally or decline. Some credit market investors, in fact, have used models of *beta-adjusted spread duration* to measure *systematic risk exposures*. The difficulty with this approach lies in estimating the betas. Empirical betas can be backed out of historical data, for example, by regressing the spread changes realized by a given bond against the average spread changes of the sector. However, it is not clear how much historical data to use for this purpose—a short sample may not give a good statistical estimate, but a long sample may include observations from a time when the security had very different characteristics. From this viewpoint, we can offer another interpretation of DTS. Essentially, DTS can be viewed as an implementation of beta-adjusted spread duration, in which the betas are provided by the market in the form of spreads. The ratio of a given issuer’s spread to the average spread for the industry gives its beta, or sensitivity, to a relative spread change across the industry.

To demonstrate this, we carried out head-to-head tests of DTS versus empirical betas using weekly spread change data from the *credit default swap (CDS)* market.⁴ In the first test, we measured the empirical betas of each issuer’s CDS with respect to its industry peer group. We then tested two different predictors for this beta—either the empirical beta from the prior period, or the ratio of issuer DTS to the industry average DTS as of the beginning of the period. In the second test, we set up long-short CDS trades between two issuers from within the same industry and investigated different approaches to setting up the hedge ratios so as to minimize the systematic risk exposures of the trades. The DTS approach was found to be superior to empirical betas for both tasks.

THE RELATION BETWEEN SPREAD VOLATILITY AND SPREAD LEVEL

We now turn our attention to the dependence of spread change behavior on spread level. Figure 2 plots the relation between systematic spread volatility and spread level using over 15 years of monthly spread change data from

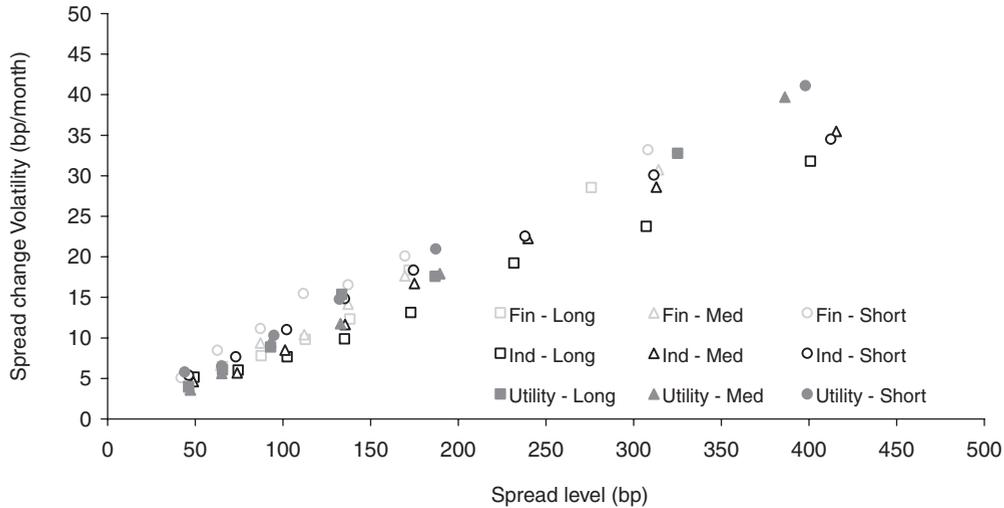

Figure 2 Systematic Spread Volatility versus Spread Level

Note: Based on monthly observations of bonds rated Aaa to B in the Barclays Capital Corporate and High-Yield Indexes, September 1989–January 2005.

Source: Barclays Capital.

U.S. credit markets, spanning investment-grade and high-yield rated bonds. The bonds in the Barclays Capital indexes for these markets were partitioned each month by sector, quality, and spread level. The average spread level for each market cell is plotted against the time-series volatility of the average absolute spread changes in each month. The results suggest that spread volatility can be closely approximated by a simple linear model of the form

$$\sigma_{\text{spread}}^{\text{absolute}}(s) \cong \theta \cdot s \tag{5}$$

This simple model provides an excellent fit to the data shown in Figure 2, with θ equal to 9.4% irrespective of sector or maturity. Hence, the results suggest that the historical volatility of systematic spread movements can be expressed quite compactly, in terms of a relative spread change volatility of about 9% per month. That is, spread volatility for a market segment trading at 50 bps should be about 4.5 bps/month, while that of a market segment at 200 bps should be about 18 bps/month. Ben Dor et al. (2007) documented a similar pattern for idiosyncratic volatility: The cross-sectional volatility of credit spread changes across a sec-

tor also exhibits a linear dependence on spread with about the same slope.

The results in Figure 2 suggest that measuring spread volatility in relative terms should be much more stable than absolute spread volatilities, and therefore forms the basis for more accurate projections of forward-looking risk. The advantage of using relative spread volatility should be particularly strong in the event of a market crisis. If we plot the absolute spread volatilities of various assets in the postcrisis period against their precrisis volatilities, we will find a marked increase across the board. Essentially, market data from the earlier period becomes useless for estimating risk in the postcrisis world. However, if we work with relative spread volatilities, we may find that they have not changed that much. The absolute spread volatility increases proportionally with the spread level, and the relative spread volatility remains stable. This relationship is illustrated in Figure 3 using data from U.S. credit markets in the period before and after the Russian crisis of 1998.

Two clear phenomena can be observed in Figure 3. First, as discussed above, most of the

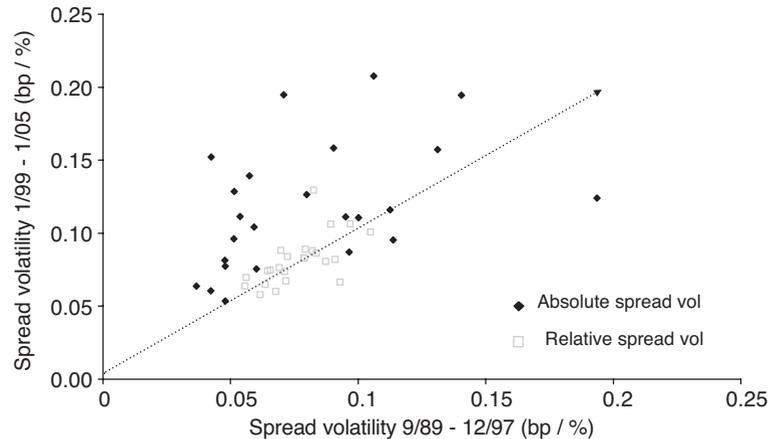

Figure 3 Absolute and Relative Spread Change Volatility before and after 1998

Note: Based on a partition of the Barclays Capital U.S. Corporate Index, 8 sectors \times 3 credit ratings. To enable the two to be shown on the same set of axes, both absolute and relative spread volatility are expressed in units with similar magnitudes. However, the interpretation is different: An absolute spread change of 0.1 represents a 10 bps parallel shift across a sector, while a relative spread change of 0.1 means that all spreads in the sector move by 10% of their current values (e.g., from 50 to 55, from 200 to 220). *Source:* Barclays Capital.

observations representing absolute spread volatilities are located far above the diagonal, pointing to an increase in volatility in the second period of the sample. In contrast, relative spread volatilities are quite stable, with almost all observations located on the 45-degree line or very close to it. This is because the pickup in volatility in the second period was accompanied by a similar increase in spreads. Second, the relative spread volatilities of various sectors are quite tightly clustered, ranging from 5%/month to a bit over 10%/month, whereas the range of absolute volatilities is much wider, ranging from 5 bps/month to more than 20 bps/month.

The results in Figure 3 exhibit the sharp discontinuity in credit market volatility that was experienced in 1998 due to the Russian crisis and the LTCM hedge fund failure. Since the introduction of DTS, global markets have provided us with ample opportunity to test the model with data from new out-of-sample crises. In both the credit crisis of 2007–2009 and the ensuing sovereign crisis that began in 2009, we have found that the DTS model has performed

admirably. In each case, a plot of precrisis vs. postcrisis volatility reveals results similar to Figure 3, showing the stability advantage of relative spread volatilities. The incorporation of spread into the projection of risk was shown to keep risk projections much more accurate than traditional absolute volatility risk measures.⁵

These results clearly indicate that absolute spread volatility is highly unstable and tends to rise with increasing spread. Computing volatilities based on relative spread change generates a more stable time series. These findings have important implications for the appropriate way of measuring credit exposures and projecting excess return volatility, which we discuss next.

DTS AND EXCESS RETURN VOLATILITY

If the volatility of both systematic and idiosyncratic spread changes is proportional to the level of spread, then equation (4) suggests two assertions regarding excess returns. First, excess return volatility should increase linearly with

DTS, where the slope represents the volatility of relative spread changes. Second, the magnitude of excess return volatility should be approximately equal across portfolios with similar DTS values, irrespective of their spread and spread duration characteristics. The results of Ben Dor et al. (2007) strongly supported both empirical predictions.

Another implication of the linear relation between spread level and spread volatility is that projecting volatility based on the current level of spread and the DTS slope from Figure 2 should be superior to using historical realizations of absolute spread changes. Specifically, using the product of DTS and the historical volatility of relative spread changes should generate better risk estimates than the product of spread duration and volatility of past absolute spread changes.

Our results confirmed that the DTS-based estimator was superior. A further indication that the DTS-based risk projection was more accurate is that it resulted in a smaller number of extreme realizations (above or below two standard deviations) than either of two estimators based on absolute spread volatility, using trailing windows of two different lengths.

Our understanding of these results is that the approach based on relative spread change volatility is able to give a more timely risk projection since it can react almost instantaneously to a change in market conditions reflected in the spread of the security. This should help the model react more quickly both to increase risk estimates at the onset of a crisis and to relax them once the turbulence subsides. Any significant widening or tightening of spreads will immediately flow through the DTS into the projection of excess return volatility.

IMPLICATIONS OF DTS FOR PORTFOLIO MANAGERS

We have highlighted above the key points that emerge from the empirical evidence supporting

the DTS paradigm. Spread changes are proportional to the level of spread. Systematic changes in spread across a sector tend to follow a pattern of relative spread change, in which bonds trading at wider spreads experience larger spread changes. The systematic spread volatility of a given sector (if viewed in terms of absolute spread changes) is proportional to the average spread in the sector; the nonsystematic spread volatility of a particular bond or issuer is proportional to its spread as well. Those findings hold irrespective of sector, duration, or time period.

There are several implications for a portfolio manager who wishes to act on these results. First, the best measure of exposure to a systematic change in spread within a given sector or industry is not the contribution to spread duration, but the contribution to DTS. At many asset management firms, the targeted active exposures for a portfolio relative to its benchmark are expressed as contribution-to-duration overweights and underweights within a sector by quality grid. Reports on the actual portfolio follow the same format. In the relative spread change paradigm, managers would express their targeted overweights and underweights in terms of contributions to DTS instead.

Second, our finding that the volatility of non-systematic return is proportional to DTS offers a simple mechanism for defining an issuer limit policy that enforces smaller positions in more risky credits. Many investors specify ad hoc weight caps by credit quality to control issuer risk. Alternatively, we can set a limit on the overall contribution to DTS for any single issuer. For example, say the product of Market value percentage \times Spread \times Duration must be 5 or less. Then, a position in issuer A, with a spread of 100 bps and a duration of five years, could be up to 1% of portfolio market value; while a position in issuer B, with a spread of 150 and an average duration of 10 years, would be limited to 0.33%. Issuer limits based on DTS and those based on market weight each have

their advantages and disadvantages; investors might want to consider some combination of the two.⁶

Third, DTS can help improve the hedging of security-vs.-security or security-vs.-market credit trades. Say a hedge fund manager has a view on the relative performance of two issuers within the same industry and would like to capitalize on this view by going long issuer A and short issuer B in a market-neutral manner. How do we define market neutrality? A typical approach might be to match the dollar durations of the two bonds, or to go long and short CDS of the same maturities with the same notional amounts. However, if issuer A trades at a wider spread than issuer B, our results would indicate that a better hedge against market-wide spread changes would be obtained by using more of issuer B, so as to match the contributions to DTS on the two sides of the trade.

Fourth, portfolio management tools such as risk and performance attribution models should represent sector exposures in terms of DTS contributions and sector spread changes in relative terms. A risk model for any asset class is essentially a set of factors that characterize the main risks that securities in that asset class are exposed to. The risk of an individual security or portfolio is computed based on its sensitivities to the various risk factors and the factor volatilities and correlations estimated from their past realizations. For credit-risky securities, traditional risk factors typically measure absolute spread changes based on a sector by quality partition that spans the universe of bonds. A risk factor specification based instead on relative spread changes has two important benefits. First, such factors would exhibit more stability over time and allow better forward-looking risk forecasts. Second, the partition by quality would no longer be necessary to control risk, and each sector can be represented by a single risk factor. This would allow managers to express more focused views, essentially trading off the elimination of the quality-based factors

with a more finely grained partition by industry. Similarly, a key goal for performance attribution models is to match the allocation process as closely as possible. If and when a manager starts to state allocation decisions in terms of DTS exposures, performance attribution should follow suit.

One practical difficulty that may arise in the implementation of DTS-based models is an increased vulnerability to pricing noise. Any small discrepancies in asset pricing should cause only small discrepancies in market values, but may potentially result in much larger variations in spreads. Consequently, managers who rely heavily on contribution-to-DTS exposures will need to implement strict quality controls on pricing.

Perhaps one of the most useful applications of DTS is in the management of core-plus portfolios that combine both investment-grade and high-yield assets. Traditionally, investment-grade credit portfolios are managed based on contributions to duration, while high-yield portfolios are managed based on market value weights. Using contributions to DTS across both markets could help bring consistency to this portfolio construction process. Skeptics may point out that in high-yield markets, especially when moving toward the distressed segment, neither durations nor spreads are particularly meaningful, and the market tends to trade on price, based on an estimated recovery value. A useful property of DTS in that context is that in the case of distressed issuers, where shorter duration securities tend to have artificially high spreads, DTS is fairly constant across the maturity spectrum, so that managing issuer contributions to DTS becomes roughly equivalent to managing issuer market weights.

The introduction of the DTS paradigm has had wide-ranging effects. It changed portfolio management practices across the industry and has been incorporated into some of the leading portfolio management analytics systems. We view it as a fundamental insight into the behavior of credit markets.

KEY POINTS

- Changes in credit spreads tend to be proportional to spread levels.
- Volatility of relative spread changes is more stable than volatility of absolute spread changes. This applies to all credit securities with a default component including corporate and sovereign issuers in developed and emerging market countries for both cash and derivatives.
- Whereas spread duration measures sensitivity to a parallel shift in spreads, DTS measures sensitivity to a relative change in spreads.
- The risk associated with credit spread exposures can therefore be managed more effectively using contributions to DTS than contributions to spread duration. This is true at the level of asset classes, industries, and individual issuers.
- Including spread in the estimation of risk can reduce the need to rely on credit ratings, allowing risk models to provide greater industry detail.

Credit Spread Decomposition

SIDDHARTHA G. DASTIDAR, PhD, CFA
Vice President, Barclays

BRUCE D. PHELPS, PhD, CFA
Managing Director, Barclays

Abstract: Credit spread decomposition refers to breaking down a bond's option-adjusted spread to Treasuries into market-wide risk premium, expected default loss, and expected liquidity cost components. Credit spread decomposition is implemented empirically by regressing a bond's option-adjusted spread on a measure of its expected default losses (credit default swap spread) and expected liquidity cost. Credit spread decomposition can help investors determine the extent to which credit spreads reflect expected default losses, liquidity costs, or a market-wide risk premium. Investors can also apply spread decomposition analysis to construct targeted hedging strategies and to identify relative value opportunities. Regulators can use spread decomposition to monitor separately the liquidity and credit risk of the institutions they supervise, and to help determine capital adequacy.

At issuance, a credit bond has a positive yield spread (i.e., a credit spread) over comparable-maturity Treasury bonds to compensate investors for the chance that the bond may default with a recovery value less than par. However, studies have documented that credit spreads are generally much larger than justified by their subsequent default and recovery experience.¹

Beyond expected default losses, a portion of the credit spread may reflect the expected *liquidity cost* to execute a roundtrip trade. This cost is typically greater for a credit bond than for a comparable-maturity Treasury bond. Investors who anticipate selling a credit bond at some point demand compensation for this cost at the time of purchase in the form of a wider spread. Another portion of the credit spread may re-

flect a market-wide risk premium demanded by risk-averse investors due to the general uncertainty associated with the timing, magnitude, and recovery of defaults and the magnitude of liquidity costs. The greater the degree of this uncertainty, or the more risk-averse the marginal investor, the more the credit spread will exceed the expected *default cost*. *Credit spread decomposition* refers to the econometric exercise of breaking down a bond's option-adjusted spread (OAS) to Treasuries into its risk premium, expected default loss, and expected liquidity cost components.

Credit spread decomposition can serve many purposes. For example, suppose an insurance company, typically a buy-and-hold investor, is considering investing in credit bonds trading

at wide spreads. The company's decision will likely depend on whether the wide spreads are due to large expected default losses, high liquidity costs, or a high market risk premium. Presumably, the company can ride out periods of high liquidity cost and risk aversion. However, if the wide spreads reflect high expected default losses, the company may decide not to invest.

This entry begins with an example highlighting the ability of credit spread decomposition to reveal additional information hidden in a bond's OAS. Next, the entry outlines the specification of the spread decomposition model and shows how it can be implemented. Following a discussion on how to interpret the model results, the entry illustrates how they can be used in portfolio management applications. The entry concludes with a discussion of some alternative specifications of the spread decomposition model.

REVEALING THE DRIVERS OF CREDIT SPREADS

To illustrate the informational value of spread decomposition, consider the historical spread

behavior of a typical investment-grade bond. As shown in Figure 1 the bond's OAS varied over time. The figure also shows the level of the issuer's credit default swap (CDS) spread—a measure of expected default losses. While movements in the bond's OAS loosely tracked changes in the issuer's CDS, there was a wide and variable gap between the two spreads, reflecting movements in risk premium and expected liquidity costs.

Figure 1 also plots the bond's expected liquidity cost over the same period. To measure a bond's liquidity cost investors can use a bond's bid-ask spread (in price terms) expressed as a percentage of the bond's bid price. This cost is labeled as the bond's liquidity cost score (LCS) by Dastidar and Phelps (2009). Much of the variability in the OAS-CDS spread gap (the *CDS-cash basis*) mirrored movements in the bond's LCS. The initial rise in the issuer's OAS was driven by both default and liquidity concerns (all three lines moved up), whereas the larger subsequent spike was mainly a liquidity event (the line plotting the LCS moved up sharply while the CDS line was little changed). This example illustrates that investors need to measure the components of OAS separately to more fully understand OAS movements.

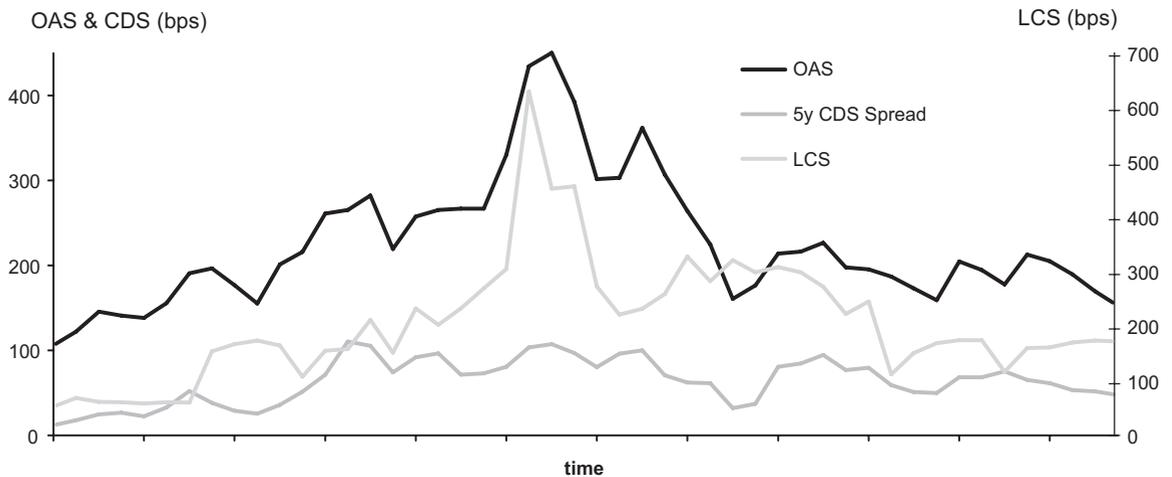

Figure 1 OAS, CDS, and LCS of a Typical Bond over Time

CREDIT SPREAD DECOMPOSITION: MODEL SPECIFICATION AND IMPLEMENTATION

To decompose credit spreads, a bond's OAS is regressed against three variables: a variable reflecting expected default cost, a variable reflecting expected liquidity cost, and a market-wide variable unrelated to the bond's attributes representing the *market-wide risk premium* demanded by investors. Conceptually, for every time t , the cross-sectional OLS regression model is:

$$OAS_{it} = \alpha_t + \beta_t \text{ExpectedDefaultCost}_{it} + \gamma_t \text{ExpectedLiquidityCost}_{it} + \eta_{it}$$

The risk premium variable (the intercept term, α) represents a market-level risk premium, not a risk premium specific to each bond. The value of the intercept is likely, but not necessarily, to be positive, reflecting that equilibrium credit spreads are typically determined at the margin by risk-averse investors.

Any bond-level risk premium is likely to be highly correlated with the bond's default cost or liquidity cost. In other words, an investor will demand a higher spread premium for a bond with a high liquidity cost as compensation for liquidity cost uncertainty. This makes it difficult to decompose a bond's spread into separate expected liquidity cost and liquidity risk premium components. The same applies to default cost and default risk premium. If default risk or liquidity risk premiums are highly correlated with default or liquidity costs, then the regression coefficients (β and γ) will be larger and/or more significant. Any part of the risk premiums that is unrelated to bond-level default and liquidity cost—in other words, a market-level risk premium—will show up in the intercept.

Credit spread decomposition is implemented empirically by running the following regression across a set of bonds (denoted by i) at a given

time t :

$$OAS_{it} = \alpha_t + \beta_t CDS_{it} + \gamma_t LCS_{it} + \eta_{it} \quad (1)$$

The LCS is used to measure bond-level expected liquidity cost. An issuer's CDS (with a similar spread duration as the bond) is used to measure its expected default cost (i.e., default probability and loss given default). If the CDS itself is illiquid, it will contain some illiquidity premium, thereby distorting results. So, only liquid CDS should be chosen. While an issuer's CDS can be used to measure the expected default cost of its bonds, other measures of expected default cost could be used in lieu of CDS. For example, some investors may use firm-specific fundamental information, equity prices, and macroeconomic data to estimate an issuer's default probability and recovery rate.

To get a sense of the value of incorporating a bond-level liquidity variable to explain the cross-sectional distribution of spreads, an investor can first estimate the model without LCS as an explanatory variable. The model can then be re-estimated adding LCS to see if the regression's fit improves and does not detract from the explanatory power of CDS. If LCS is a useful explanatory variable, adding LCS as a regressor should produce an improvement in the adjusted R^2 and a significant (and positive) LCS coefficient, with little disturbance to the significance and magnitude of the CDS coefficient.

INTERPRETING THE RESULTS OF THE CREDIT SPREAD DECOMPOSITION MODEL

The estimated regression coefficients can be used to break down the average OAS into the three spread components in terms of basis points. For example, suppose the average OAS, CDS, and LCS are 2.09%, 1.14%, and 0.73%, respectively. In addition, suppose the estimated coefficients of CDS and LCS are 0.67 and 1.41,

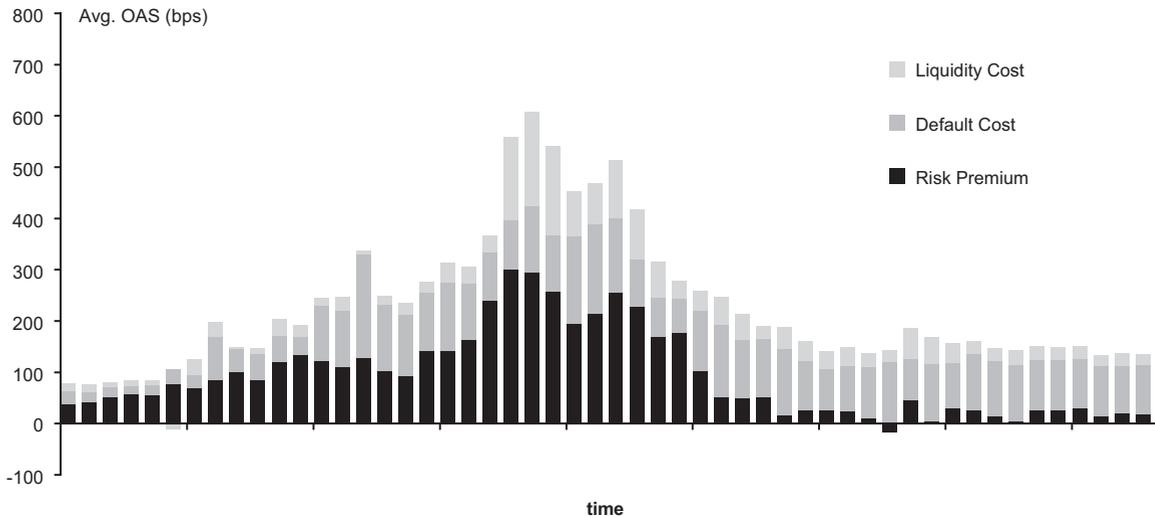

Figure 2 Relative Contribution of Default Cost, Liquidity Cost, and Risk Premium over Time

respectively. A variable's contribution to the average OAS can be determined by multiplying the average value of the variable by its estimated regression coefficient (e.g., $1.41 \times 0.73\%$ is the contribution of LCS to the average OAS). Repeating spread decomposition at different time periods can show fluctuations in the relative contributions to OAS of the three components over time as shown in Figure 2.

When liquidity is abundant, LCS might not play an important role in explaining spread differences across bonds. In fact, adding LCS to the regression may not meaningfully improve the R^2 . In contrast, when liquidity conditions deteriorate, adding LCS to the regression will likely improve the R^2 .

As discussed, the regression intercept captures the portion of (average) spread that is independent of CDS and LCS. The market risk premium is likely to be, at times, an important contributor to the level of OAS. The time series can be used as an indicator of the variation of the market risk premium—or risk aversion—in the credit market. When the intercept explains a relatively high proportion of OAS, this suggests that systematic market factors, rather than bond-specific factors, are driving spreads. This may occur because of very high levels of aggre-

gate risk aversion or because the market is pricing bonds with little concern for issuer-specific information. When the intercept explains a relatively low proportion of OAS, this suggests that bond-specific factors are driving spreads.

The regression coefficients for both CDS and LCS are expected to be positive. While the relationship of CDS with OAS is naturally tight, it may not be as close as one might think. Since default risk for high-grade bonds has been very low over long periods of time, a relatively large proportion of the OAS is likely liquidity-related.

APPLICATIONS OF CREDIT SPREAD DECOMPOSITION

The parameter estimates from the spread decomposition model can be used in a variety of portfolio management applications. Active portfolio managers can use spread decomposition to take positions in specific bonds with large liquidity or default components, depending on their views about how these components are likely to evolve. Regulators can use spread decomposition to monitor separately the liquidity and credit risk embedded in the credit

portfolios of the institutions they supervise, which can help determine capital adequacy.

Presented below is a discussion of two important applications of credit spread decomposition: identifying bonds that may be trading “rich” or “cheap,” and allowing the manager to construct hedges that target specific drivers of OAS fluctuations.

Identifying Relative Value

So far, credit spread decomposition analysis has been described using contemporaneous data to attribute OAS levels to default and liquidity cost components at a given time. However, investors can apply spread decomposition analysis to *ex ante* investment decisions as well.

In principle, spread decomposition should help identify *relative value* opportunities. A bond’s OAS can be compared with its estimated OAS using the parameters from the spread decomposition model. If the actual OAS is wider than the estimated OAS, it suggests that the bond is trading too wide, and vice versa. This may be a signal that the bond’s OAS may change to correct this “mispricing.”

To examine whether the realized residuals $\hat{\eta}_{i,t}$, from (1) can help predict future OAS changes, one can examine whether the bond’s future OAS changes are of the opposite sign to the sign of the residual by running the following regression and testing to see if the θ ’s are negative.

$$\Delta OAS_{it,t+j} = \alpha_t + \theta_t \hat{\eta}_{it} + \delta_t \text{MonthDummy}_t + e_{it} \quad (2)$$

Hedging a Credit Bond Portfolio

One method to determine a hedge for a credit is to use regression to examine the historical relationship between the bond’s OAS and potential hedge variables. The issuer’s CDS may be an effective hedge targeted against changes in expected default losses. Since movements in the volatility index (VIX) are closely related to changes in LCS,² VIX futures can potentially

be used as a *credit hedging* instrument to target spread changes related to changes in liquidity.

If an investor seeks to hedge the default or liquidity components separately, then the contribution to OAS in basis points from the credit spread decomposition model (in differences—discussed below) determines the appropriate hedge ratio for each component. Of course, the success of such a hedge depends on the goodness of fit and whether the historical relationship will hold in the future.

ALTERNATIVE CREDIT SPREAD DECOMPOSITION MODELS

There are alternative formulations of the credit spread decomposition model. As discussed earlier, the analysis has ignored explicit bond-level risk premium variables. Instead, it assumes that any bond-level risk premium is highly related to either the expected liquidity cost or the expected default cost. An alternative model can include a term representing a bond-level liquidity risk premium. This additional term reflects compensation demanded by investors for the risk that the actual cost at liquidation may be different from the expected liquidity cost as measured by the current LCS. A bond’s LCS volatility over the prior 12 months can be considered a measure of liquidity risk. For example, two bonds may have the same LCS today, but bond A may have a much more volatile LCS history than bond B. An investor may view bond A as having a riskier liquidity cost and demand an OAS premium versus bond B, all else equal.

The equation below shows the spread decomposition model incorporating a bond-level liquidity risk factor, $LCSVol_{i,t}$. Generally, the results may show that $LCSVol_{i,t}$ is highly significant, but absorbs part of the effect of LCS, thereby not improving the regression’s adjusted R^2 substantially.

$$OAS_{it} = \alpha_t + \beta_t CDS_{it} + \gamma_t LCS_{it} + \phi_t LCSVol_{it} + \delta_t \text{MonthDummy}_t + \eta_{it} \quad (3)$$

The credit spread decomposition model can also be estimated in differences to check if changes in the liquidity and default proxies affect changes in OAS (i.e., contemporaneous returns). The regression model below details the specification, where ΔOAS_{it} , ΔCDS_{it} , and ΔLCS_{it} refer to changes in a bond's characteristics in consecutive periods. As described above, this model of spread decomposition can be used for designing targeted hedges.

$$\Delta OAS_{it} = \alpha_t + \beta_t \Delta CDS_{it} + \gamma_t \Delta LCS_{it} + \delta_t \text{MonthDummy}_t + \eta_{it} \quad (4)$$

Finally, the spread decomposition model may be susceptible to outliers, especially since default and liquidity are arguably more important considerations for higher spread bonds. To check this, one can run log regressions (e.g., the dependent variable is $\ln(OAS)$ instead of OAS , similarly for the independent variables), as shown below. If the conclusions from the log model are unchanged, this would indicate that outliers are not driving the results.

$$\ln(OAS_{it}) = \alpha_t + \beta_t \ln(CDS_{it}) + \gamma_t \ln(LCS_{it}) + \eta_{it} \quad (5)$$

KEY POINTS

- Credit spread decomposition refers to breaking down a bond's option-adjusted spread (OAS) to Treasuries into market risk premium, expected default loss, and expected liquidity cost components.
- To decompose credit spreads, a bond's OAS is regressed on a measure of its expected default cost (CDS) and expected liquidity cost (LCS).
- Credit spread decomposition can help credit investors determine the extent to which spreads reflect expected default losses, high liquidity costs, or a high market-wide risk premium, and make portfolio decisions accordingly.
- Investors can also apply spread decomposition analysis for determining targeted hedging strategies and to help identify relative value opportunities.

Credit Derivatives and Hedging Credit Risk

DONALD R. VAN DEVENTER, PhD

Chairman and Chief Executive Officer, Kamakura Corporation

Abstract: The credit crisis of 2007–2009 in the United States and Europe and the collapse of the *Japanese bubble* in the 1990–2002 period show that, without hedging credit risk, the largest financial institutions in the world are very likely to fail. Many trillions of dollars of taxpayer bailouts have put the credit quality of the United States and Japan at risk. The solution to this financial institutions' risk management problem and the related sovereign risk problem is hedging with respect to macro factor movements. Hedging interest rate movements has a 40-year history, but now the focus has turned to a longer list of macro factors like home prices, commercial real estate prices, oil prices, commodity prices, foreign exchange rates, and stock indices. This hedging capability is now widely available in best practice enterprise risk management software. Stress testing with respect to macro factors is now a mandatory requirement of the European Central Bank and U.S. bank regulators.

In this entry, we examine practical tools for hedging *credit risk* at both the transaction level and the portfolio level, focusing on the interaction between the credit modeling technologies and traded instruments that would allow one to mitigate credit risk. We start with a discussion linking credit modeling and credit portfolio management in a practical way. We then turn to the credit default swap market as a potential hedging tool. Finally, the state of the art is discussed: hedging transaction level and portfolio credit risk using hedges that involve macroeconomic factors that are traded in the marketplace.

CREDIT PORTFOLIO MODELING: WHAT'S THE HEDGE?

One of the reasons that the popular value-at-risk (VaR) concept has been regarded as an incomplete risk management tool is that it provides little or no guidance on how to hedge if the VaR indicator of risk levels is regarded as too high. In a more subtle way, the same criticisms apply to many of the key modeling technologies that are popular in financial markets, like the *copula approach* to the simulation of credit portfolios. In this entry we summarize the

Figure 1 Cyclical Rise and Fall in 5-Year Reduced Form Default Probabilities: Citigroup and Ford Motor Company, 2006–2011

virtues and the vices from a hedging perspective of both various credit modeling techniques and credit derivative instruments traded in the marketplace. One of the key issues that requires a lot of attention in credit portfolio modeling is the impact of the business cycle on default probabilities. Default probabilities rise and fall when the economy weakens and strengthens. This is both obvious and so subtle that almost all commercially available modeling technologies ignore it. It's easy to talk about it and hard to do.

Figures 1 and 2 show the cyclical rise and fall in 5-year reduced-form default probabilities for Citigroup and Ford Motor Company for the periods 1990–2005 and 2006–2011.¹ The figures show the obvious correlation in default probabilities for both companies as they rise or fall in the 1990–1991 recession and in the recession spanning 1999–2003, depending on the sector, but the greatest correlation is in the *credit crisis* period of 2007–2009. Over the full 1990–2011 period, their respective 5-year default probabilities have a simple correlation of 45.2%.

With this common knowledge as background, we begin with the hedging implications of the *Merton model* at the individual transaction and portfolio level (see Merton, 1974).

THE MERTON MODEL AND ITS VARIANTS: TRANSACTION-LEVEL HEDGING

As of this writing, every publicized commercial implementation of the Merton model or its variants has one principal assumption in common: The only random factor in the model is the “value of company assets.” Regardless of the variety of Merton model used, all models of this type have the following attributes in common when the value of company assets rises:

- Stock prices rise.
- Debt prices rise.
- Credit spread falls.
- Default probability falls.

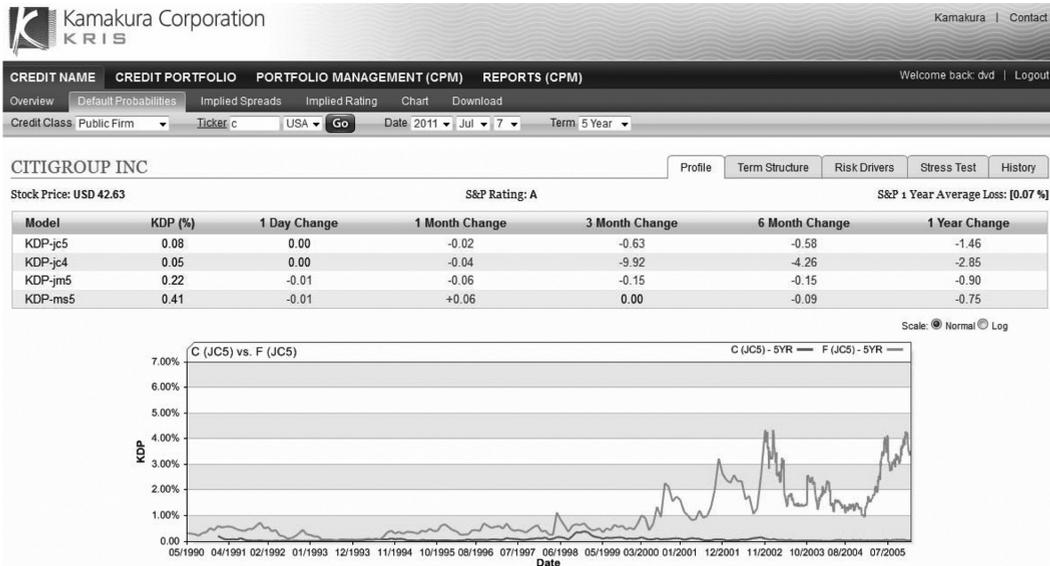

Figure 2 Cyclical Rise and Fall in 5-Year Reduced Form Default Probabilities: Citigroup and Ford Motor Company, 1990–2005

From a theoretical point of view, there are three obvious ways to think about hedging in the Merton context:

- Hedge a long position in the debt of the firm with a short position in the assets of the company.
- Hedge a long position in the debt of the firm with a short position in the common stock of the company.
- Hedge a long position in the debt of the firm with a short position in another debt instrument of the company.

The first hedging strategy is consistent with the assumptions of the Merton model and all of its commercial variants, because assets of the firm are assumed to be traded in perfectly liquid efficient markets with no transactions costs. Unfortunately, for most industrial companies, this is a very unrealistic assumption. Investors in Ford Motor Company cannot go long or short auto plants in any proportion. The third hedging strategy is also not a strategy that one can use in practice, although the credit derivative instruments we discuss in the next section provide a variation on this theme.

From a practical point of view, shorting the common stock is the most direct hedging route and the one that combines a practical hedge and one consistent with the model theory. Unfortunately, however, even this hedging strategy has severe constraints that restrict its practical use. Specifically, even if the Merton model or its variant is true, mathematically, the first derivative of the common stock price with respect to the value of company assets approaches zero as the company becomes more and more distressed. When the value of company assets is well below the amount of debt due, the common stock will be trading just barely above zero. One would have to short more and more equity to offset further falls in debt prices, and at some point a hedging strategy that shorts even 100% of the company's equity becomes too small to fully offset the risk still embedded in debt prices. In short, even if the Merton model is literally true, the model fails the hedging test ("What's the hedge?") for deeply distressed situations.

What about companies that are not yet severely distressed? Jarrow and van Deventer (1998, 1999), analyzed a 9-year weekly data

series of new issue fixed rate bond spreads collected by First Interstate Bancorp, which at the time was the seventh largest bank holding company in the United States. Over the sample period used by Jarrow and van Deventer, First Interstate's debt ratings varied from AA to BBB. They analyzed the debt and equity hedge ratios produced by the Merton model (and its variants) and tested for biases that would reduce hedging errors. The results of that analysis showed that a common stock hedge in the opposite direction of that indicated by the Merton model (and its variants) would have improved results. That is, one should have gone long the equity even if one is long the debt, not short the equity. Jarrow and van Deventer are careful to point out that this strategy is certainly not recommended. The reason for this finding was simple: During the 9-year weekly data series beginning in 1984, credit spreads and stock price changes move in the direction predicted by the Merton model less than 45% of the time. Van Deventer and Imai (2003) obtain similar results over a much larger sample.

Jarrow and van Deventer make the point that the Merton model is clearly missing key variables that would allow credit spreads and equity prices to move in either the same direction or the opposite direction as these input variables change. None of the Merton models in commercial use have this flexibility and therefore any hedge ratios they imply are quite suspect.

What about companies that are not investment grade but do not yet fall in the "severely distressed" category? It is in this sector that individual transaction hedging using Merton-type intuition is potentially the most useful. Most of the research that has been done in this regard has been done on a proprietary basis on Wall Street. Even if the Merton model hedging is useful for companies in the BB and B ratings grade, how effective can it be in protecting the owner of a bond that once was rated AA but sinks to a distressed CCC? Whether or not hedging errors in the AA to BBB and CCC ratings

ranges more than offset hedging benefits in the BB and B range is an important question. Modern corporate governance requires that users of the Merton model have evidence that it works in this situation, rather than relying on a belief that it works. On September 12, 2005, the *Wall Street Journal* reported on the hundreds of millions of dollars that were lost by arbitrageurs using Merton-type hedges on Ford and General Motors when both firms were downgraded by the major rating agencies.²

There are a few more points that one needs to make about the Merton model and all of its commercial variants when it comes to transaction level hedging:

- The Merton model default probability is not an input in this hedging calculation for the same reason that the return on the common stock is not an input in the Black-Scholes options model. The Merton model and all of its commercial variants incorporate all possible probabilities of default that stem from every possible variation in the value of company assets.
- Loss given default is also not an input in this hedging calculation because all possible loss given defaults (one for each possible ending level of company asset value) are analyzed by the Merton model and in turn have an impact on the calculated hedge ratio.

These insights are not widely recognized by analysts who consider hedging using the Merton technology. Given the value of company assets, we can calculate the Merton hedge ratio directly with no need for a default probability estimate or a loss given default estimate. If instead we are given the Merton (or its variants) default probability, we do not know the hedge ratio without full disclosure of how the default probability was derived. Any failure to make this disclosure is a probable violation of the Basel II capital accords from the Basel Committee on Banking Supervision.

THE MERTON MODEL AND ITS VARIANTS: PORTFOLIO-LEVEL HEDGING

One of the attractive things about the Merton model, in spite of the limitations mentioned above, is its simple intuition. We know that the basic businesses of Ford and General Motors are highly correlated, so it is a small logical step to think about how the assets of the two companies must be closely correlated. One has to make a very substantial set of additional assumptions if one wants to link the macroeconomic factors that drive correlated defaults to the value of company assets in the Merton framework or any of its one-factor commercial variants. Let's assume away those complexities and assume that we know the returns on the assets of Ford have a 0.25 correlation with the returns on the assets of General Motors. Note that the 0.25 correlation does not refer to

- The correlation in the default probabilities themselves.
- The correlation in the events of default, defined as the vector of 0s and 1s at each time step where 0 denotes no default and 1 denotes default.

These are different and mathematically distinct definitions of correlation. Jarrow and van Deventer (1998, 1999) show some of the mathematical links between these different definitions of correlation. Jarrow and van Deventer (2005) formalize these results.

Once we have the correlation in the returns on the value of company assets, we can simulate correlated default as follows:

- We generate N random paths for the values of company assets of GM and Ford that show the assumed degree of correlation.
- We next calculate the default probability that would prevail, given that level of company assets, at that point in time in the given scenario.
- We then simulate default/no default.

For any commercial variant of the Merton model, an increase in this "asset correlation" results in a greater degree of bunching of defaults from a time perspective. This approach was a common first step for analysts evaluating first-to-default swaps and collateralized debt obligations because they can be done in common spreadsheet software packages with a minimum of difficulty.

There are some common pitfalls to beware of in using this kind of analysis that are directly related to the issues raised about the Merton framework and its commercial variants:

- If one is using the original Merton model of risky debt, default can happen at only one point in time: the maturity date of the debt. This assumption has to be relaxed to allow more realistic modeling.
- If one is using the "down and out option" variation of the Merton model, which dates from 1976, one has to specify the level of the barrier that triggers default at each point in time during the modeling period.

Unless one specifically links the value of company assets to macroeconomic factors, the portfolio simulation has the same limitations from a hedging point of view as a single transaction. As explained earlier, the hedge using a short position in the common stock would not work for deeply troubled companies from a theoretical point of view and it does not work for higher rated credits (BBB and above) from an empirical point of view.

If one does link the value of company assets to macroeconomic factors, there is still another critical and difficult task one has to undertake to answer the key question: "What's the hedge?" One needs to convert the single-period, constant interest rates Merton model or Merton variant to a full valuation framework for multiperiod fixed-income instruments, many of which contain a multitude of embedded options (like a callable bond or a line of credit). One of the many lessons of the *Wall Street Journal* article cited above and subsequent

experience in 2007–2009 is easy to summarize: This approach to hedging and simulating credit risk (called the “copula approach” as well as the Merton approach) simply did not work. Salmon (2009) called the Merton/copula approach the “formula that killed Wall Street” via the \$945 billion in credit losses that resulted from the credit crisis.³

What if we want to use the Merton/copula approach in spite of its role in recent losses? As Lando (2004) discusses, this is a large set of non-trivial analytical issues to deal with. Most importantly, moving to a multiperiod framework with random interest rates leads one immediately to the *reduced form model* approach, where it is much easier for the default probability models to be completely consistent within the valuation framework. We turn to that task now.

Reduced-Form Models: Transaction-Level Hedging

One of the many virtues of the reduced form modeling approach is that it explicitly links factors driving default probabilities, like interest rates and other macroeconomic factors, to the default probabilities themselves. Just as important, the reduced form framework is a multiperiod, no-arbitrage valuation framework in a random interest rate context. Once we know the default probabilities and the factors driving them, credit spreads follow immediately, as does valuation. Valuation, even when there are embedded options, often comes in the form of analytical closed-form solutions. More complex options require numerical methods that are commonly used on Wall Street. The ability to stress test portfolio values and portfolio losses with respect to *macro factor* movements is now required by the European Central Bank and by U.S. bank regulators via two programs: the Comprehensive Capital Assessment Review and the Supervisory Capital Assessment Program. The later program, required of the top 19 U.S. financial institutions in 2009, mandated stress tests with respect to

changes in *home prices*, real gross domestic product, and the unemployment rate.

Suffice it to say that for any simulated value of the risk factors driving default, there are two valuations that can be produced in the reduced form framework. The first valuation is the value of the security in the event that the issuer has not defaulted. This value can be stress tested with respect to the risk factors driving default to get hedge ratios with respect to the nondiversifiable risk factors. The second value that is produced is the value of the security given that default has occurred. In the reduced form framework of Duffie and Singleton (1999) and Jarrow (2001), this loss given default can be random and is expressed as a fraction of the defaultable instrument one instant prior to default.

These default-related jumps in value have two components. The first part is the systematic (if any) dependence of the loss given default or recovery rate on macroeconomic factors. The second part is the issuer-specific default event, since (conditional on the current values of the risk factors driving default for all companies) the events of default are independent. At the individual transaction level, this idiosyncratic company-specific component can only be hedged by shorting a defaultable instrument of the same issuer or a credit default swap of that issuer.

At the portfolio level, this is not necessary. We explain why next.

Reduced-Form Models: Portfolio-Level Hedging

One of the key conclusions of a properly specified reduced form model is that the default probabilities of each of N companies at a given point in time are independent, conditional on the values of the macroeconomic factors driving correlated defaults. That is, as long as none of the factors causing correlated default have been left out of the model, then by definition, given the value of these factors, default is

independent. This is an insight of Jarrow, Lando, and Yu (2005).

This powerful result means that individual corporate credit risk can be diversified away, leaving only the systematic risk driven by the identified macroeconomic variables. This means that we can hedge the portfolio with respect to changes in these macroeconomic variables just as we do in every hedging exercise: We mark to market the portfolio on a credit-adjusted basis and then stress test with respect to one macroeconomic risk factor. We calculate the change in value that results from the macroeconomic risk factor shift and this gives us the “delta.” We then can calculate the equivalent hedging position to offset this risk. This is a capability that is present in modern enterprise-wide risk management software.⁴

This exercise needs to be done for a wide range of potential risk factor shifts, recognizing that some of the macroeconomic risk factors are in fact correlated themselves. Van Deventer, Imai, and Mesler (2004) outline procedures for doing this in great detail.

We turn now to commonly used credit-related derivative instruments and discuss what role they can play in a hedging program.

CREDIT DEFAULT SWAPS AND HEDGING

Credit default swaps in their purest form provide specific credit protection on a single issuer. They are particularly attractive when the small size of a portfolio (in terms of issuer names) or extreme concentrations in a portfolio rule out diversification as a vehicle for controlling the idiosyncratic risk associated with one portfolio name.

Generally speaking, credit default swaps should only be used when diversification does not work. As we discuss in a later section, dealing directly in the macroeconomic factors that are driving correlated default is much more efficient both in terms of execution costs and in

terms of minimizing counterparty credit risk. An event that causes a large number of corporate defaults over a short time period would also obviously increase the default risk of the financial institutions that both lend to them and act as intermediaries in the credit default swap market. This insight was not widely appreciated as recently as 2006, but it is now. The bankruptcy of Lehman Brothers on September 15, 2008, the March 2008 rescue of Bear Stearns, and the September 2008 rescues of Merrill Lynch (by Bank of America with U.S. government support) and Morgan Stanley (by the Federal Reserve) have convinced any doubters of the importance of counterparty credit risk in the credit default swap market. As of this writing, only 14 dealers are registered to clear credit default swaps with the Depository Trust and Clearing Corporation.⁵

Many researchers have begun to find that credit spreads and credit default swap quotations are consistently higher than actual credit losses would lead one to expect.⁶ How can such a “liquidity premium” persist in an efficient market? From the perspective of the insurance provider on the credit default swap, in the words of one market participant, “Why would we even think about providing credit insurance unless the return on that insurance was a lot greater than the average losses we expect to come about?” That preference is simple enough to understand, but why doesn’t the buyer of the credit insurance refuse to buy insurance that is “overpriced”?

One potential explanation is related to the lack of diversification that individual market participants face even if their employers are fully diversified. An individual fund manager may have only 10–20 fixed income exposures and a bonus pool that strictly depends on his or her ability to outperform a specific benchmark index over a specific period of time. One default may devastate the bonus, even if the fund manager in 1 billion repeated trials may in fact outperform the benchmark. The individual has more reason to buy single-name credit

insurance than the employer does because (1) his or her work-related portfolio is much less diversified than the entire portfolio of the employer, (2) the potential loss of the bonus makes him or her much more risk averse than the employer, and (3) the employer is much less likely to be aware that the credit insurance is (on average) overpriced than the individual market participant. Jarrow, Li, Mesler, and van Deventer (2007) have quantified the magnitude of this premium and shown that factors as diverse as company size (bigger firms get smaller spreads) and location (Japanese firms get smaller spreads) affect the premium of CDS spreads over default risk. These premiums are available daily via the Thomson Reuters "Credit Views" page.⁷

A more important concern with credit default swap hedging is the very thin trading volume in the CDS market in the aftermath of the credit crisis. A study⁸ found the following:

- Only 241 corporate reference names averaged more than 5 trades per day.
- Only 63 reference names averaged more than 10 trades per day.
- Only 14 reference names averaged more than 15 trades per day.
- No reference names averaged more than 23 trades per day.

Given these low volumes, there is a serious risk of market manipulation that should give any potential hedger great concern.

PORTFOLIO- AND TRANSACTION-LEVEL HEDGING USING TRADED MACROECONOMIC INDICES

The instantaneous probability of default can be specified as a linear function of one or more macroeconomic factors. An example is the case where the default intensity is a linear function of the random short-term rate of interest

r and a macroeconomic factor with normally distributed return Z :

$$\lambda(t) = \lambda_0 + \lambda_1 r(t) + \lambda_2 Z(t)$$

The constant term in this expression is an idiosyncratic term that is unique to the company. Random movements in the short rate r and the macroeconomic factor Z will cause correlated movements in the default intensities for all companies whose risk is driven by common factors. The default intensity has a term structure like the term structure of interest rates, and this entire term structure moves up and down with the business cycle as captured by the macroeconomic factors. The parameters of this reduced form model can be derived by observable histories of bond prices of each counterparty or from observable histories of credit derivatives prices using enterprise-wide risk management software.

Alternatively, a historical default database can be used to parameterize the term structure of default probabilities using discrete instead of continuous default probabilities, just as discrete interest rates are used in practice based on yield curve movements in continuous time. The most common approach to historical default probability estimation uses logistic regression. For each company, monthly observations are denoted 0 if the company is not bankrupt in the following month and 1 if the company does go bankrupt in the next month. Explanatory variables X_i are selected and the parameters α and β , which produce the best fitting predictions of the default probability using the following logistic regression formula:

$$P[t] = 1/[1 + \exp(-\alpha - \sum_{i=1}^n \beta_i X_i)]$$

By fitting this logistic regression for each default probability on the default probability term structure, one can build the entire cumulative and annualized default probability term structures for a large universe of corporations. Figure 3 shows the cumulative term structure of

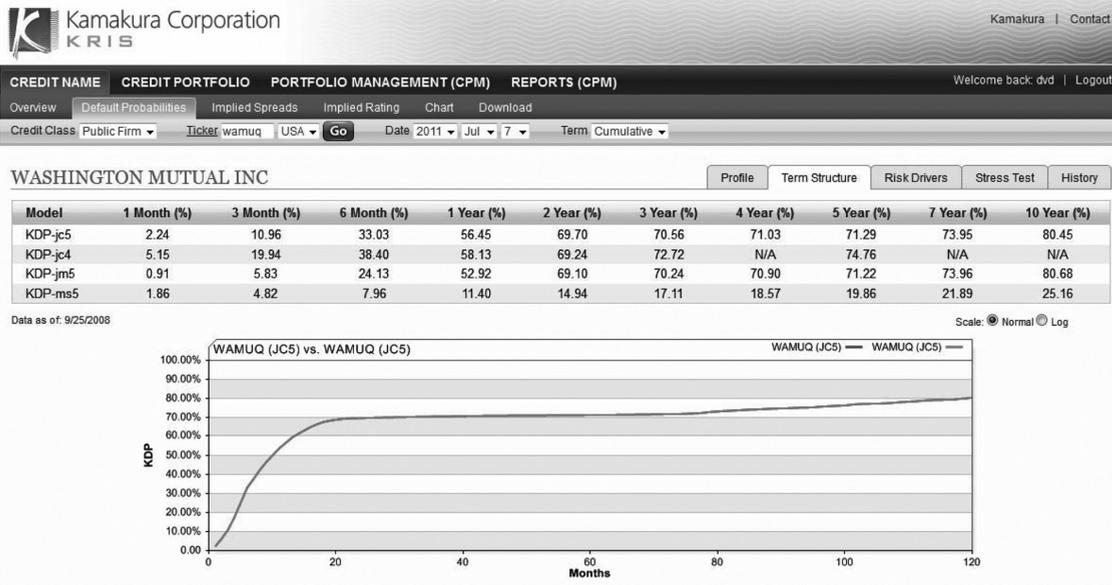

Figure 3 Cumulative Term Structure of Default Probabilities for Washington Mutual: September 2008, One Day Prior to Default

default probabilities for Washington Mutual, just prior to its failure in September 2008.

Alternatively, one can annualize the entire term structure of default probabilities for easy comparison with credit spreads and credit default swap quotations. The resulting curve is downward sloping for high-risk credits like Washington Mutual (see Figure 4).

The key advantage of the reduced-form approach is that critical macroeconomic factors can be linked explicitly to default probabilities as explanatory variables. The result is a specific mathematical link like the linear function of the pure Jarrow reduced form model or the logistic regression formula used for historical database fitting. The logistic regression formula is very powerful for simulating forward since it always produces default probability values between zero and 100%. These values can then be converted to the linear Jarrow form for closed-form mark-to-market values for every transaction in a portfolio.

Van Deventer, Imai, and Mesler (2004) then summarize how to calculate the macroeco-

nomie risk factor exposure as follows. The Jarrow model is much better suited to hedging credit risk on a portfolio level than the Merton model because the link between the (N) macro factor(s) M and the default intensity is explicitly incorporated in the model. Take the example of Washington Mutual, whose probability of default is driven by interest rates and home prices, among other things. If $M(t)$ is the macro factor defined as the one-year change in home prices, it can be shown that the size of the hedge that needs to be bought or sold to hedge one dollar of risky debt zero coupon debt with market value v under the Jarrow model is given by

$$\begin{aligned} \partial v_l(t, T : i) / \partial M(t) = & -[\partial \gamma_l(t, T) / \partial M(t) \\ & + \lambda_2(1 - \delta_i)(T - t) / \\ & \sigma_m M(t)] v_l(t, T : i) \end{aligned}$$

The variable v is the value of risky zero-coupon debt and γ is the liquidity discount function representing the illiquidities often observed in the debt market. There are similar formulas in the Jarrow model for hedging

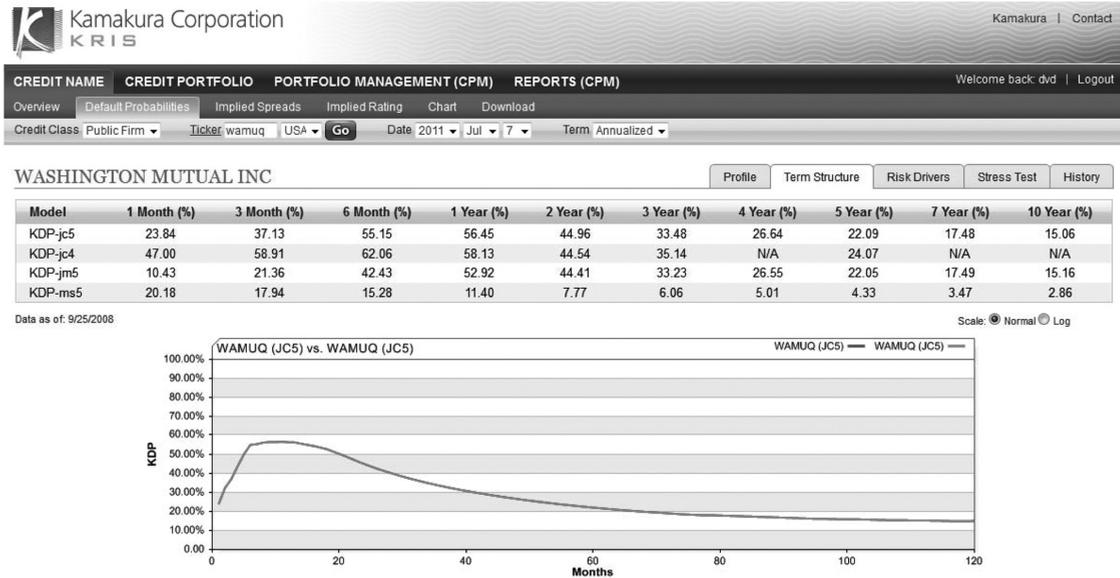

Figure 4 Annualized Term Structure of Default Probabilities for Washington Mutual: September 2008, One Day Prior to Default

coupon-bearing bonds, defaultable caps, floors, credit derivatives, and so on.

In practice, these hedge ratios are derived from a sophisticated simulation on “best practice” enterprise-wide risk management software. Van Deventer and Imai (2003) show that the steps in hedging the macro factor risk for any portfolio are identical to the steps that a trader of options has been taking for 30 years (hedging the net position with a long or short position in the common stock underlying the options):

- Calculate the change in the value (including the impact of interest rates on default) of all retail credits with respect to interest rates.
- Calculate the change in the value (including the impact of interest rates on default) of all small business credits with respect to interest rates.
- Calculate the change in the value (including the impact of interest rates on default) of all major corporate credits with respect to interest rates.

- Calculate the change in the value (including the impact of interest rates on default) of all bonds, derivatives, and other instruments.
- Add these “delta” amounts together.
- The result is the global portfolio “delta,” on a default-adjusted basis, of interest rates for the entire portfolio.
- Choose the position in interest rate derivatives with the opposite delta.
- This eliminates interest rate risk from the portfolio on a default-adjusted basis.

We can replicate this process for any macroeconomic factor that impacts default, such as home prices, exchange rates, stock price indices, oil prices, the value of class A office buildings in the central business district of key cities, and so on.

Most importantly,

- We can measure the default-adjusted transaction level and portfolio risk exposure with respect to each macroeconomic factor.
- We can set exposure limits on the default-adjusted transaction level and portfolio risk

exposure with respect to each macroeconomic factor.

- We know how much of a hedge would eliminate some or all of this risk.

The reason this analysis is so critical to success in credit risk portfolio management is the all-pervasiveness of correlated risk. Let us put aside the 2007–2009 credit crisis and look at other recent history. Take the Japan scenario. At the end of December 1989, the Nikkei stock price index had reached almost 39,000. Over the course of the next 14 years, it traded as low as 7,000. Commercial real estate prices fell by more than 60%. Single-family home prices fell in many regions for more than 15 consecutive years. More than 135,000 small businesses failed. Six of the 21 largest banks in Japan were nationalized in a span of two years. How would this approach have worked in Japan?

First of all, fitting a logistic regression for small businesses in Japan over this period shows that the properly specified inputs for the Nikkei and the yen/U.S. dollar exchange rates have *t*-score equivalents of more than 45 standard deviations from zero in a logistic regression. By *stress testing* a small business loan portfolio with this knowledge, we would have known how many put options on the Nikkei and put options on the yen were necessary to fully or partially offset credit-adjusted mark-to-market loan losses, just as the Federal Deposit Insurance Corporation announced it was doing in its 2003 Loss Distribution Model.⁹

This same approach works with

- Retail loan portfolios
- Small business loan portfolios
- Large corporate loan, bond, derivative, and other portfolios
- Sovereign and other government exposures

If common factors are found to drive each class of loans, then we have enterprise-wide correlations in defaults. An identical approach in the U.S. market would have spared many financial institutions tens of billions in losses that

resulted from an inability to do the stress tests described above and that are now mandated by the U.S. government and the European Central Bank.

The key to success in this analysis is a risk management software package that can handle it.¹⁰ What is also important in doing the modeling is to recognize that macroeconomic factors that are exchange traded (such as the S&P 500, home price futures, etc.) are much preferred to similar indicators that are not traded (such as the Conference Board index of leading indicators or the unemployment rate).

If one takes this approach, total balance sheet credit hedging is very practical

- Without using credit derivatives
- Without using first-to-default swaps
- Without using Wall Street as a counterparty from a credit risk point of view

All of these benefits are critical to answer the key question of “What’s the hedge?”

KEY POINTS

- It is not enough to know only the default risk of a counterparty. Over the full portfolio, a financial institution needs to know the answer to the question “What is the hedge?” if the measured credit risk is uncomfortably large.
- The major U.S. (2007–2009) and Japanese (1990–2002) financial institutions required government bailouts in the trillions of dollars because of their inability to measure and hedge macro factor risks like those of home price movements and commercial real estate price movements.
- The Merton model is a logical place to start thinking about how to hedge because of its simple structure and focus on the value of company assets.
- Unfortunately, for theoretical reasons alone, hedging in the Merton framework does not work for a company that is highly distressed. A perfect hedge could easily require a short

- position of more than 100% of the shares of outstanding common stock.
- The only practical and accurate approach to hedging credit risk is the reduced form modeling approach.
 - Hedging with credit default swaps is not practical because of the high degree of counterparty credit risk that is now obvious in the wake of the 2007–2009 credit crisis and the effective failures of investment banking firms like Bear Stearns, Lehman Brothers, Morgan Stanley, and Merrill Lynch. Moreover, trading volume in the credit default swap market is now so thin that large trades cannot be efficiently executed, and the risk of market manipulation is very high.
 - The reduced form approach explicitly links macro factors to both observable bond and CDS prices and to a historical default database. A similar approach links macro factors to credit spreads and recovery rates. The recovery on a mortgage that is in default is an example. Obviously, it depends on the value of the house that is collateral.
 - *Delta hedging* of aggregate portfolio exposure to these macro factors that drive credit risk is done in best practice enterprise-wide risk management software.
 - This modern application of stress testing, applied to a longer list of macro factors than interest rates alone, is not just theory. It is now mandated by the European Central Bank and U.S. regulatory authorities.

Derivatives Valuation

No-Arbitrage Price Relations for Forwards, Futures, and Swaps

ROBERT E. WHALEY, PhD

Valere Blair Potter Professor of Management and Co-Director of the Financial Markets Research Center, Owen Graduate School of Management, Vanderbilt University

Abstract: The three key factors that drive the valuation of a financial asset are risk, return, and timing of cash flows. A fundamental assumption in valuation is that in the absence of costless arbitrage opportunities, if two investments whose risk, return, and timing of cash flow properties are exactly the same are identified, they must have the same price in the marketplace. Otherwise, market participants can make free money by simultaneously selling the more expensive one and buying the cheaper one. This principle allows for the development of no-arbitrage price relations for forwards, futures, and swaps. The price of a futures contract is identical to the price of a forward contract in an environment in which short-term interest rates are known. In addition, a swap contract is nothing more than a portfolio of forward contracts. Hence, if a forward contract can be valued, a swap can be valued. The forward price and the underlying spot price are inextricably linked by the net cost of carry relation.

Exchange-traded and over-the-counter (OTC) derivatives contracts are traded worldwide. Of these, the lion's share is plain-vanilla forwards, futures, and swaps. The purpose of this entry is to develop no-arbitrage price relations for forwards, futures, and swap contracts. In doing so, we rely only on the assumption that two perfect substitutes must have the same price. The two substitutes, in this case, are a forward/futures contract and a levered position in the underlying asset. The key to understanding the forward/futures valuation lies in identifying the net cost of carrying (i.e., "buying and holding") an asset. We begin therefore with a discussion of carry costs/benefits. We then proceed by developing a number of important *no-arbitrage rela-*

tions governing forward and futures prices. Finally, we show that, since a swap contract is an exchange of future payments at a price agreed upon today, it can be valued as a portfolio of forward contracts.

UNDERSTANDING CARRY COSTS/BENEFITS

Derivative contracts are written on four types of assets—stocks, bonds, foreign currencies, and commodities. The derivatives literature contains seemingly independent developments of derivative valuation principles for each type

of asset. Generally speaking, however, the valuation principles are not asset-specific. The only distinction among assets is how carry costs/benefits are modeled.

The *net cost of carry* refers to the difference between the costs and the benefits of holding an asset. Suppose a breakfast cereal producer needs 5,000 bushels of wheat for processing in two months. To lock in the price of the wheat today, he can buy it and carry it for two months. One carry cost common to all assets is the opportunity cost of funds. To come up with the purchase price, he must either borrow money or liquidate existing interest-bearing assets. In either case, an interest cost is incurred. We assume this cost is incurred at the risk-free rate of interest. Beyond interest cost, however, carry costs vary depending upon the nature of the asset. For a physical asset or commodity such as wheat, we incur storage costs (e.g., rent and insurance). At the same time, certain benefits may accrue. By storing wheat we may avoid some costs of possibly running out of our regular inventory before two months are up and having to pay extra for emergency deliveries. This is called convenience yield. Thus, the net cost of carry for a commodity equals interest cost plus storage costs less convenience yield, that is,

$$\begin{aligned} \text{Net carry cost} &= \text{Cost of funds} + \text{Storage cost} \\ &\quad - \text{Convenience yield} \end{aligned}$$

For a financial asset or security such as a stock or a bond, the carry costs/benefits are different. While borrowing costs remain, securities do not require storage costs and do not have convenience yields. What they do have, however, is income (yield) that accrues in the form of quarterly cash dividends or semiannual coupon payments. Thus, the net cost of carry for a security is

$$\text{Net carry cost} = \text{Cost of funds} - \text{Income}$$

Carry costs and benefits are modeled either as *continuous rates* or as discrete flows. Some costs/benefits such as the cost of funds (i.e., the risk-free interest rate) are best modeled as continuous rates. The dividend yield on a broadly based stock portfolio, the interest income on a foreign currency deposit, and the lease rate on gold also fall into this category. Other costs/benefits such as warehouse rent payments for holding an inventory of grain, quarterly cash dividends on individual common stocks, and semiannual coupon receipts on a bond are best modeled as discrete cash flows. Below we provide the continuous rate and discrete flow cost of carry assumptions. For ease of exposition, we first introduce some notation. The current price of the asset is denoted S . Its price at future time T is \tilde{S}_T , where the tilde denotes the future asset price is uncertain. The opportunity cost of funds (i.e., the risk-free rate of interest) is assumed to be a constant, continuous rate and is denoted r . If we borrow to buy the asset today, we will owe Se^{rT} at time T .

Continuous Rates

The types of assets whose carry costs are typically modeled as constant, continuous rates include broadly based stock index portfolios, foreign currencies, and gold. Assume that we borrow at the risk-free rate of interest to buy a stock index portfolio that pays cash dividends at a constant continuous rate i . If we buy one unit of the index today and reinvest all dividends immediately as they are received in more shares of the index portfolio, the number of units of the index portfolio will grow to exactly e^{iT} units at time T . Alternatively, if we want exactly one unit of the index on hand at time T , we buy only e^{-iT} units today at a cost of Se^{-iT} . The terminal value of our investment in the index portfolio at time T will be \tilde{S}_T . The loan value has accrued from Se^{-iT} to $Se^{-iT}e^{rT} = Se^{(r-i)T}$. After repaying the loan, the terminal portfolio value will be $\tilde{S}_T - Se^{(r-i)T}$. Within this continuous

rate framework, the net cost of carry rate of an index portfolio equals the difference between the risk-free rate of interest r and the dividend yield rate i . The situation for a foreign currency is identical. If we borrow at the domestic risk-free rate, buy a foreign currency, and then invest the currency at the prevailing foreign risk-free rate, the net cost of carry rate equals the difference between the domestic interest rate r and the foreign interest rate i . Similarly, if we borrow at the risk-free rate, buy gold, and then lend it in the marketplace, the net cost of carry rate equals the difference between the interest rate r and the lease rate on gold i . Within this framework, the total cost of carry paid at time T is

$$\text{Net carry cost}_T = S[e^{(r-i)T}] - 1 \quad (1)$$

To illustrate, assume that the S&P 500 index is currently at a level of 1,100 and pays dividends at the continuous rate of 3% annually. Assume also that “shares” of the S&P 500 index can be purchased and sold at the index level (i.e., one share currently costs \$1,100). Suppose that an investor wants exactly 3,000 shares of the S&P 500 index on hand in five days. How many shares of the S&P 500 index must the investor buy today if all dividends paid are reinvested in more shares of the index portfolio?

If the investor wants 3,000 shares of the index on hand in five days, the investor needs to buy $3,000e^{-0.03(5/365)} = 2,998.77$ shares today. Over the first day, the number of shares will grow by a factor $e^{0.03(1/365)}$ due to the reinvestment of dividends, bringing the number of shares to $2,998.77e^{0.03(1/365)} = 2,999.01$. Over the second day, the number of shares will again grow by a factor $e^{0.03(1/365)}$ due to the reinvestment of dividends, bringing the number of shares to 2,999.26. Since the dividends are being paid at a constant, continuous rate, we know the original number of shares purchased will grow to exactly 3,000 shares by the end of day 5 (i.e., $3,000e^{0.03(5/365)}e^{-0.03(5/365)} = 3,000$), as is shown in the following table.

Day	Index Level	Units of Index	Value of Index Position
0	1,100.00	2,998.77	3,298,644
1	1,160.00	2,999.01	3,478,856
2	1,154.00	2,999.26	3,461,146
3	1,145.00	2,999.51	3,434,435
4	1,170.00	2,999.75	3,509,712
5	1,175.00	3,000.00	3,525,000

Discrete Flows

For most other types of assets including stocks with quarterly cash dividends and bonds with semiannual coupon payments, noninterest carry costs/benefits are best modeled as discrete flows. Suppose a stock promises to pay n known cash dividends in the amount I_i at time t_i , $i = 1, \dots, n$ between now and future time T . If we borrow S to cover the purchase price of the stock and reinvest all cash dividends as they are received at the risk-free rate of interest, the terminal value of our position will be

$$\tilde{S}_T + \sum_{i=1}^n I_i e^{r(T-t_i)} - S e^{rT}$$

In this instance, the net cost of carry at time T is

$$\text{Net carry cost}_T = S(e^{rT} - 1) - \sum_{i=1}^n I_i e^{r(T-t_i)}$$

For coupon-bearing bonds, the expressions are the same; however, S denotes the bond price and I_i at time t_i , $i = 1, \dots, n$ denote coupon payments.

To illustrate, an investor buys 10,000 shares of ABC Corporation and carries that position for 90 days. ABC's current share price is \$50, and the stock promises to pay a \$4 dividend in exactly 30 days. What will be the value of the portfolio when the investor unwinds in 90 days, assuming that the risk-free rate of interest is 5%? As Table 1 shows, the initial investment in 10,000 shares of ABC costs \$500,000. The investor financed the entire purchase price with risk-free borrowings, hence the initial investment is \$0. In 90 days, the investor has three components to the portfolio. First, the investor owns 10,000 shares valued at \tilde{S}_T a share.

Table 1 Future Value of Asset That Pays Discrete Cash Flows

Trade	Initial Investment	Value on Day T
Buy stock	$-50(10,000)$	$10,000\tilde{S}_T$
Borrow funds	500,000	$-500,000e^{0.05(90/365)} = -506,202.54$
Receive cash dividends on day t , and reinvest at risk-free rate until day T		$40,000e^{0.05(60/365)} = 40,330.12$
Value of position	0	$10,000\tilde{S}_T - 506,202.54 + 40,330.12$

Next, the investor must repay the \$500,000 in risk-free borrowings plus interest at a cost of \$506,202.54. Finally, the investor received cash dividends of \$4 a share or \$40,000 on day 30, which the investor invested immediately in risk-free discount bonds. Dividends plus accrued interest amount to \$40,330.12 on day T . Thus, the total value of the portfolio in 90 days is $10,000\tilde{S}_T - 506,202.54 + 40,330.12$.

Summary and Some Guidelines

Carry costs/benefits are the known costs/benefits associated with holding an asset over a fixed period of time. In general, they consist of two components—(1) interest and (2) income (in the case of a financial asset) or storage (in the case of a physical asset). The interest component is always expressed as a rate. If we buy an asset today with borrowed funds, we will owe e^{iT} per unit of the asset on day T . Income and noninterest costs are expressed either as a continuous proportion of the asset price or as discrete cash flows, depending upon the nature of the underlying asset. Firms potentially have four different sources of price risk—equity risk, interest rate risk, foreign exchange risk, and commodity price risk. Table 2 presents terminal values of leveraged asset positions using the net cost of carry assumption appropriate to each asset category.

VALUING FORWARDS

With the concept of net cost of carry in hand, we now turn to valuing forward contracts. A forward is a contract that requires its seller to

deliver the underlying asset on future day T at a price agreed upon today. We denote today's forward price as f . Its price on day T is denoted \tilde{f}_T . A forward with no time remaining to expiration must have the same price as the underlying asset, that is, $\tilde{f}_T = \tilde{S}_T$ as shown in Figure 1. Otherwise, a costless arbitrage profit is possible by buying the asset and selling the forward, or vice versa. The purpose of this section is to derive the value of a forward contract relative to its underlying asset price prior to time T under the continuous and discrete net carry cost assumptions.

Continuous Rates

To establish the price of a forward today, consider a U.S. corporation that needs to make a EUR 1,000,000 payment in T days and wants to lock in the U.S. dollar value of this payment today. The firm can accomplish this goal in two ways.

First, it can borrow U.S. dollars and buy euros today at the spot exchange rate S , and then carry the position for T days. To have one euro on hand in T days, they need to buy e^{-iT} units today where i is the risk-free interest rate in Europe. To finance the entire purchase today, they need to borrow Se^{-iT} . The repayment of the loan will occur in T days, and the principal plus interest will amount to $Se^{-iT}e^{iT}$ per euro where r is the U.S. risk-free interest rate.

Second, it can negotiate the price of a T -day forward contract with its bank. Under the terms of the forward contract, the firm will buy 1,000,000 euros in T days at a cost of f per euro. No money changes hands today. In making its

Table 2 Future value at time T of a leveraged asset position using continuous rate/discrete flow net cost of carry assumptions. All assets are assumed to incur interest cost at a constant continuous rate r .

Asset Type	Recommended Model	Terminal Value	Explanation of Noninterest Carry Costs/Benefits
Equity Individual stock or narrowly based stock portfolio	Discrete flow	$\tilde{S}_T - (Se^{rT} - FVI)$	For individual common stocks or narrowly based stock indexes, income accrues in the form of discrete cash dividends I_i paid at time t_i , and the dividends are carried forward until time T at the risk-free interest rate r , that is, $FVI = \sum_{i=1}^n I_i e^{r(T-t_i)}$
Stock portfolio	Continuous rate	$\tilde{S}_T - Se^{(r-i)T}$	For broadly based stock portfolios, income accrues at a constant, continuous dividend yield rate i .
Bonds	Discrete flow	$\tilde{S}_T - (Se^{rT} - FVI)$	For coupon-bearing bonds, income accrues in the form of discrete coupon payments I_i paid at time t_i , and the coupons are carried forward until time T at the risk-free interest rate r , that is, $FVI = \sum_{i=1}^n I_i e^{r(T-t_i)}$
Currency	Continuous rate	$\tilde{S}_T - Se^{(r-i)T}$	For foreign currency deposits, income accrues at a constant, continuous foreign rate of interest i .
Commodity	Discrete flow	$\tilde{S}_T - (Se^{rT} - FVI)$	For most physical commodities, storage costs (e.g., warehouse rent and insurance) are paid and convenience yield accrues. In this case, FVI is the future value of convenience yield less the future value of the discrete storage cost payments, that is, $FVI = FV(\text{Convenience yield}) - FV(\text{Storage costs})$
			While storage costs can be modeled as discrete flows, convenience yield (e.g., the lease rate on gold) may be modeled as a rate.

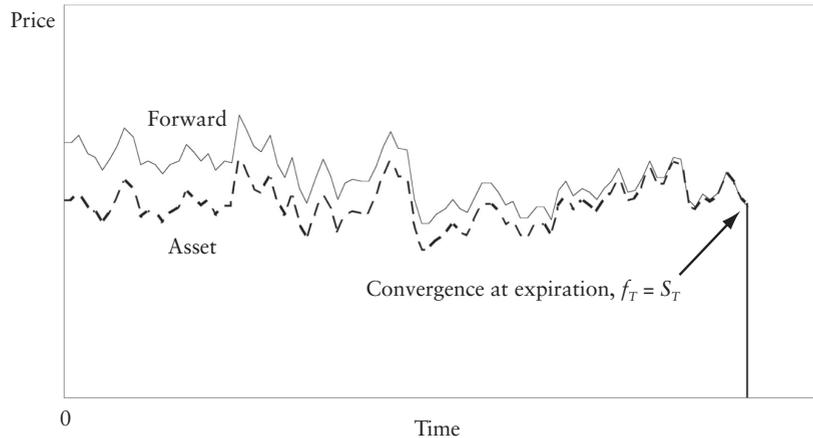

Figure 1 Price paths of forward contract and its underlying asset through time. Price convergence occurs at expiration.

decision about which strategy to take, the firm will compare the forward price with the future value had the euros been purchased today and carried until day T . If f exceeds $Se^{(r-i)T}$, the firm will buy the euros in the spot market and carry them. If f is less than $Se^{(r-i)T}$, the firm will buy the forward contract. Both alternatives provide the firm with EUR 1,000,000 in T days at a price locked in today. Since they are perfect substitutes, they must have the same price. The value of a forward in a constant continuous net cost of carry framework is

$$f = Se^{(r-i)T} \quad (2)$$

The relation (2) is sometimes called the *net cost of carry relation*. When the prices of the forward and the asset are such that (2) holds exactly, the forward market is said to be at full carry. Unless costless arbitrage is somehow impeded, we can be assured that the forward market will always be at full carry. Suppose, for an instant in time, $f > Se^{(r-i)T}$. Such a condition implies that there is a costless arbitrage opportunity. We should immediately sell the forward and buy the asset, financing the purchase of the asset with risk-free borrowing. Table 3 shows the outcome. With no investment today, we earn a certain outcome of $f - Se^{(r-i)T} > 0$ on day T . Naturally, the market cannot be in equilib-

rium. The costless arbitrage activity would continue until the selling pressure on the forward price and the buying pressure on the asset price makes the arbitrage profit equal to 0. Where no arbitrage opportunity exists, the cost of carry relation (2) holds.

The net cost of carry relation (2) is written in future value form, since both sides of the equation are values on day T , as shown in Table 3. The relation can also be expressed in present value form. Multiplying both sides of (2) by the discount factor e^{-rT} , we get

$$fe^{-rT} = Se^{-iT} \quad (3)$$

What (3) says is that the prepaid *forward contract*, fe^{-rT} , equals the initial cost of the asset position, Se^{-iT} .

Table 3 Costless Arbitrage Trades Where $f > Se^{(r-i)T}$

Trades	Initial Investment	Value on Day T
Buy e^{-iT} units of asset	$-Se^{-iT}$	\tilde{S}_T
Borrow (sell risk-free bonds)	Se^{-iT}	$-Se^{(r-i)T}$
Sell forward contract		$-(\tilde{S}_T - f)$
Net portfolio value	0	$f - Se^{(r-i)T}$

Discrete Flows

In the event that income or noninterest carry costs are more appropriately modeled as discrete cash flows, the net cost of carry relation is

$$f = Se^{rT} - FVI$$

where FVI is the future value of the promised income receipts. If the underlying asset is a physical asset, the future value of the income, FVI , may be negative as a result of storage cost payments. The relation can also be written in its present value form,

$$fe^{-rT} = S - PVI$$

where PVI is the present value of the promised income receipts, that is, $PVI = FVIe^{-rT}$. The prepaid forward price equals $S - PVI$, where the underlying asset distributes discrete known cash flows through time.

To illustrate, let's compute the value of a forward contract on a hypothetical dividend-paying stock, HAL Company. Specifically, we want to value a six-month forward contract on 3,000 shares of this company, assuming that the current share price is \$120 and that a \$3 cash dividend will be paid in two months and then again in five months. Assume the risk-free rate of interest is 5%. Since the cash dividend payments are discrete cash inflows, the cost of carry relation given by (1) is the most appropriate. The future value of the first dividend payment is $3e^{0.05(4/12)}$ given by (1) and the future value of the second dividend is $3e^{0.05(1/12)}$. The future value of all income received during the forward contract's life is therefore

$$FVI = 3e^{0.05(4/12)} + 3e^{0.05(1/12)} = 6.06$$

The value of the forward contract is therefore

$$f = 120e^{0.05(6/12)} - 6.06 = 116.97 \text{ per share}$$

or \$350,910 in total.

Hedging with Forwards

Before turning to futures contract valuation, it is worth considering the no-arbitrage portfolio in Table 3 more closely. It contains important

Table 4 Hedging a Stock Portfolio Using a Forward Contract

Trades	Initial Investment	Value on Day T
Own stock portfolio. Reinvest all dividend income into more shares of stocks.	$-S$	$\tilde{S}_T e^{iT}$
Sell e^{-iT} forward contract.	0	$-(\tilde{S}_T - f)e^{iT}$
Net portfolio value	0	fe^{iT}

intuition regarding hedging risk. Suppose that we hold a stock portfolio and fear that the market will decline over the next few months. To avoid the risk of a stock market decline, we can sell our stocks and buy risk-free bonds. Alternatively, we can sell a forward contract on our stock portfolio. These alternatives are perfect substitutes.

To see this, assume that our portfolio is sufficiently broad-based that it is reasonable to assume that the dividend yield is a constant continuous rate, i . If all dividend income is invested in more units of the stock portfolio, one unit in the stock portfolio today will grow to e^{iT} units on day T , as we discussed earlier and illustrated in Table 4. To hedge the price risk exposure of e^{iT} units of the stock portfolio on day T , we need to sell e^{iT} forward contracts today. The value of this forward position will be $-(\tilde{S}_T - f)e^{iT}$ on day T . Once the positions are netted, the terminal value of the portfolio is fe^{iT} . Note that the value is certain. The forward price, the dividend yield rate, and the hedge period horizon (i.e., the life of the forward contract) are all known on day 0. To see that the return on the hedged portfolio equals the risk-free return, substitute the net cost of carry relation, $f = Se^{(r-i)T}$, in the expression for the terminal value of the portfolio in Table 4. The net terminal value is $fe^{iT} = Se^{(r-i)T}e^{iT} = Se^{rT}$, exactly the amount we would have had if the stock portfolio had been liquidated and invested in risk-free bonds at the outset.

Table 5 Perfect Substitutes Implied by the Net Cost of Carry Relation

Position 1		Position 2
Buy asset/sell forward	=	Buy risk-free bonds (lend)
Buy risk-free bonds (lend)/buy forward	=	Buy asset
Buy asset/sell risk-free bonds (borrow)	=	Buy forward
Sell asset/buy forward	=	Sell risk-free bonds (borrow)
Sell risk-free bonds (borrow)/sell forward	=	Sell asset
Sell asset/buy risk-free bonds (lend)	=	Sell forward

Summary

A long forward position is a perfect substitute for buying the asset using risk-free borrowings. Consequently, the price of a forward equals the price of the asset plus net carry costs. But this is only one possible combination of positions in the asset, the forward, and risk-free bonds. Table 5 shows all possible pairings. Using the net cost of carry relation, we can demonstrate why Position 1 is a perfect substitute for Position 2 in all six rows of the table. A full understanding of each relation will prove invaluable in understanding valuation and risk management problems.

VALUING FUTURES

Futures contracts are like forward contracts, except that price movements are *marked-to-market* each day rather than waiting until contract expiration and having a single, once-and-for-all settlement. If the marking-to-market produces a gain during the futures contract's life, the gain can be reinvested in interest-bearing securities. Conversely, if the marking-to-market produces a loss, the loss must be covered with either existing interest-bearing assets or borrowing at the risk-free interest rate.

To distinguish between buying a forward and buying a futures, consider the futures position cash flows shown in Table 6. As we discussed earlier, a forward contract purchased today has a value $\tilde{S}_T - f$ on day T . In contrast, a futures contract is marked to market each day, and the daily gains/losses gather interest. If risk-free

rate of interest is 0%, the terminal value of the futures position (i.e., the sum of the mark-to-market gain/loss column) is the same as the terminal value of the forward position. If risk-free rate of interest is greater than 0%, however, the value of the futures position on day T may be greater or less than the terminal value of the forward position, depending on the path that futures prices follow over the life of the contract.

To illustrate, suppose that an investor needs £1,000,000 in three days and wants to lock in the price today. Suppose also that a three-day forward contract on British pounds is priced at \$1.60 per pound and that a British pound futures contract with three days remaining to expiration also has a price of \$1.60. Let's compare the terminal values of a long forward position with a long futures position at the end of three days assuming the domestic risk-free rate is 5%. Assume that the futures prices over

Table 6 Cash Flows of Long Futures Positions through Time

Day t	Futures Price	Mark-to-Market Gain/Loss on Day t	Value of Gain/Loss on Day T
0	F		
1	\tilde{F}_1	$\tilde{F}_1 - F$	$(\tilde{F}_1 - F)e^{r(T-1)}$
2	\tilde{F}_2	$\tilde{F}_2 - \tilde{F}_1$	$(\tilde{F}_2 - \tilde{F}_1)e^{r(T-2)}$
...			...
t	\tilde{F}_t	$\tilde{F}_t - \tilde{F}_{t-1}$	$(\tilde{F}_t - \tilde{F}_{t-1})e^{r(T-t)}$
...			...
$T-1$	\tilde{F}_{T-1}	$\tilde{F}_{T-1} - \tilde{F}_{T-2}$	$(\tilde{F}_{T-1} - \tilde{F}_{T-2})e^r$
T	\tilde{F}_T	$\tilde{F}_T - \tilde{F}_{T-1}$	$\tilde{F}_T - \tilde{F}_{T-1}$
Total		$\tilde{F}_T - \tilde{F}_1$	$\sum_{t=1}^T (\tilde{F}_t - \tilde{F}_{t-1})e^{r(T-t)}$

the next three days are \$1.71, \$1.67, and \$1.70, respectively.

The terminal value of a long forward position is simply the exchange rate on day 3, \$1.70, less the forward price, \$1.60, times one million, \$100,000, exactly equal to the sum of the mark-to-market gains/losses on the long futures position. The terminal value of the long futures position when the mark-to-market gains/losses are invested/financed at the risk-free rate of interest, however, is \$100,024.66, as is shown in the following table.

Day t	Futures Price	Mark-to-Market Gain/Loss on day t	Value of Gain/Loss on Day T
0	1.60		
1	1.71	110,000.00	110,030.14
2	1.67	-40,000.00	-40,005.48
3	1.70	30,000.00	30,000.00
Total		100,000.00	100,024.66

In general, the terminal value of a long forward and a long futures will be different. The reason that the terminal values are different is that the terminal value of the futures position depends on how the futures price evolves through time. Other futures price paths will produce different terminal values. If, for example, the futures price had been \$1.51 on day 1 rather than \$1.71, the terminal value of the futures position would have been \$99,997.26,

below (not above) the \$100,000 terminal value of the long forward.

Telescoping Futures Position

Interestingly, the fact that a long forward position does not have the same terminal value of a long futures position does not imply that the forward and futures prices are different. Indeed, as we will show shortly, they are equal. We can control the effect of the reinvestment of the mark-to-market proceeds by creating a “telescoping futures position.”

A telescoping futures position is created as follows. We begin, on day 0, with e^{-rT} futures contracts. Since we enter the position at the close of day 0, the marked-to-market gain for the day is 0. In preparation for day 1, we increase the size of the futures position by a factor e^r . At the end of day 1, the futures position is marked-to-market, generating proceeds of $e^{-r(T-1)}(\tilde{F}_1 - F)$. If this gain/loss is carried forward at the risk-free interest rate until day T , the terminal gain/loss will be $e^{-r(T-1)}(\tilde{F}_1 - F)e^{r(T-1)} = \tilde{F}_1 - F$, as shown in Table 7. On day 2, the position is again increased by a factor e^r and is marked-to-market at $e^{-r(T-2)}(F_2 - F_1)$. Carrying this amount forward to day T , we have $e^{-r(T-2)}(\tilde{F}_2 - \tilde{F}_1)e^{r(T-2)} = (\tilde{F}_2 - \tilde{F}_1)$, and so on. Because the number of futures is chosen to exactly offset the accumulated interest factor on the daily mark-to-market gain/loss, there will be exactly one futures contract on hand on day

Table 7 Cash Flows of Telescoping Futures Position Providing Same Terminal Value as Forward Position on Day T

Day t	Futures Prices	No. of Futures Contracts	Mark-to-Market Gain/Loss on Day t	Value of Gain/Loss on Day T
0	F	e^{-rT}		
1	\tilde{F}_1	$e^{-r(T-1)}$	$e^{-r(T-1)}(\tilde{F}_1 - F)$	$e^{-r(T-1)}(\tilde{F}_1 - F)e^{r(T-1)} = (\tilde{F}_1 - F)$
2	\tilde{F}_2	$e^{-r(T-2)}$	$e^{-r(T-2)}(\tilde{F}_2 - \tilde{F}_1)$	$\tilde{F}_2 - \tilde{F}_1$
...			...	
t	\tilde{F}_t	$e^{-r(T-t)}$	$e^{-r(T-t)}(\tilde{F}_t - \tilde{F}_{t-1})$	$\tilde{F}_t - \tilde{F}_{t-1}$
...			...	
$T-1$	\tilde{F}_{T-1}	e^{-r}	$e^{-r}(\tilde{F}_{T-1} - \tilde{F}_{T-2})$	$\tilde{F}_{T-1} - \tilde{F}_{T-2}$
T	\tilde{F}_T	1	$\tilde{F}_T - \tilde{F}_{T-1}$	$\tilde{F}_T - \tilde{F}_{T-1}$
Total				$\tilde{F}_T - F = \tilde{S}_T - F$

T , and the value of the futures position will be $S_T - F$. Assuming that the futures and forward contracts expire at the same time, the telescoping futures position will have exactly the same terminal value as the long forward position.

Using an illustration, let's compare terminal values of long forward and long telescoping futures positions. Suppose that an investor needs £1,000,000 in three days and wants to lock in the price today. Suppose also that a three-day forward contract on British pounds is priced at \$1.60 per pound and that a British pound futures contract with three days remaining to expiration also has a price of \$1.60. Assume that the domestic risk-free interest rate is 5% and that the futures prices over the next three days are \$1.71, \$1.67, and \$1.70, respectively.

As in the previous illustration, the terminal value of a long forward position is the exchange rate on day 3, \$1.70, less the forward price, \$1.60, times one million, or \$100,000. Because the initial futures position has less than 1 million units, the total of the mark-to-market gains/losses column is less than \$100,000. The terminal value of the telescoping futures position when the mark-to-market gains/losses are invested/financed at the risk-free rate of interest is exactly \$100,000, as is shown in the following table:

Day	Futures Price	Number of Units	Mark-to-Market Gain/Loss on day t	Value of Gain/Loss on Day T
0	1.60			
1	1.71	999,726.06	109,969.87	110,000.00
2	1.67	999,863.02	-39,994.52	-40,000.00
3	1.70	1,000,000.00	30,000.00	30,000.00
Total			99,975.35	100,000.00

The dynamic rebalancing of the futures position within the telescoping strategy ensures that the outcome is exactly the same as a long forward position.

Equivalence of Forward and Futures Prices

The fact that a long telescoping futures position has a terminal value of $\tilde{S}_T - F$ and that a long forward position has a terminal value of $S_T - F$ implies that the futures price and forward price must be equal to each other.¹ If they are not, a costless arbitrage profit would be possible by selling the forward and entering a long telescoping position in the futures (if $f > F$) or by buying the forward and entering a short telescoping position in the futures (if $f < F$). Given the equivalence of forward and futures prices, the valuation equations for a futures contract are the same as those of the forward, that is,

$$F = f = Se^{(r-i)T} \quad (4)$$

if all carry costs are constant continuous rates, and

$$F = f = Se^{rT} - FVI \quad (5)$$

if noninterest carry costs are discrete.

Let's illustrate how to short sell stocks synthetically using stock futures. Retail investors in the U.S. often find it costly to short sell shares of common stock. Consequently, stocks futures were recently launched. Assume that an investor wants to short sell a particular stock over the next T days. Its current share price is S , and a cash dividend of D has been declared and will be paid in t days. Let's demonstrate that selling a telescoping position in share futures is equivalent to short selling the stock.

First, the value in T days of a short position in the stock must be identified. Short selling a share of the stock generates proceeds of S . Assume that an investor can take the proceeds from the short sale and invest them at the risk-free rate of interest. In addition, the stock pays a cash dividend of D on day t . The investor is responsible for paying the cash dividend. On day T , the value of each security position

in the portfolio is as reported in the following table:

Trades	Initial Investment	Value on Day T
Short sell stock. Must pay cash dividends, if any.	S	$-\tilde{S}_T - De^{r(T-t)}$
Buy risk-free bonds	$-S$	Se^{rT}
Net portfolio value	0	$Se^{rT} - De^{r(T-t)} - \tilde{S}_T$

The net portfolio value on day T is $Se^{rT} - De^{r(T-t)} - \tilde{S}_T$.

From the discussion above, we know that selling a telescoping position in the share futures has a terminal value of $F - \tilde{S}_T$. But, from valuation equation (5), we know that, in the absence of costless arbitrage opportunities, $F = Se^{rT} - De^{r(T-t)}$. Substituting, we find that the value of the short futures position on day T is $Se^{rT} - De^{r(T-t)} - \tilde{S}_T$, an amount identical to that of the short stock position.

HEDGING WITH FUTURES

The telescoping futures position has implications in terms of hedging with futures contracts. For the hedge to be completely effective, the number of futures must equal the number of units of the underlying asset on day T . Under the continuous carry cost assumption, we know that one unit of the asset grows to e^{iT} units on day T . We also know that telescoping futures positions that starts with e^{-rT} futures contracts today has a single contract at time T . Consequently, to hedge the long asset position in Table 4, our futures hedge would start off with being short $e^{-(r-i)T}$ futures contract on day 0, and would scale up by a factor of e^r contracts per day over the life of the hedge. Assuming the futures expires on day T , the terminal value of the short telescoping position would be $-(\tilde{S}_T - F)e^{iT}$ and the net terminal value of the hedged portfolio would be Fe^{iT} . Substituting the

net cost of carry relation (4), the net terminal value of the hedged portfolio may be written Se^{rT} , which shows that hedging using a short telescoping futures position is equivalent to liquidating the asset position and buying risk-free bonds. The day-to-day increase in the size of the futures position by the interest factor e^r undoes the effects of interest on the daily marking to market of the futures gains/losses. In practice, this dynamic, day-to-day adjustment is called tailing the hedge.

SUMMARY

Futures contracts are like forward contracts except that price movements are marked to market daily. Because these daily gains/losses are allowed to accrue interest until the end of the contract's life, a long futures position will not in general have the same terminal value as a long forward position. The effects of the interest accrual on the mark-to-market gains/losses can be undone, however, using a telescoping futures position. Each day t , the number of futures is set equal to $e^{-r(T-t)}$ for each unit of the underlying asset at the end of the hedging interval. Set in this way, the terminal value of a long telescoping position in the futures equals the terminal value of a long forward. From a costless arbitrage perspective, therefore, the following are perfect substitutes:

Long telescoping futures position = Long forward position

Short telescoping futures position = Short forward position

The telescoping futures strategy also has implications for hedging. To undo the effects of interest on the daily marking to market of the futures gains/losses when the life of the futures matches the hedging horizon T , the size of a futures hedge starts at a level equal to the present value of the number of terminal units of that asset, that is, e^{-rT} for each unit of the asset and increases in size by a factor of e^r each day.

IMPLYING FORWARD NET CARRY RATES

Thus far, we have examined forward/futures contracts with a single maturity. A casual examination of the financial pages, however, shows multiple maturities for the same underlying asset. In these situations, we can use the net cost of carry relation (2) to deduce implied forward cost of carry rates.

VALUING SWAPS

A *swap* contract is an agreement to exchange a set of future cash flows. A plain-vanilla swap is usually regarded to be an exchange of a fixed payment for a floating payment, where the floating payment is tied to some reference rate, index level, or price. Like a forward contract, the underlying asset can be anything from a financial asset such as a stock or a bond to a physical asset such as crude oil or gold. Also, like a forward contract, a swap involves no up-front payment.

The key information needed to value a swap contract is the *forward curve* of the underlying asset and the zero-coupon yield curve for risk-free bonds. The forward curve refers to the relation between the price of a forward contract on the underlying asset and its time to expiration or settlement. Where the time to expiration is 0, the forward price equals the prevailing spot price. Figure 2 shows two possible forward curve relations. A *normal forward curve* is upward sloping, and an *inverted forward curve* is downward sloping. For financial assets, the slope will depend on the net difference between the risk-free rate and the income received on the underlying asset. Thus, a normal forward curve will arise in markets where the interest rate is greater than the income rate, and an inverted forward curve will arise in markets where the interest rate is less than the income rate. For physical assets or commodities, the nature of the forward curve depends also on

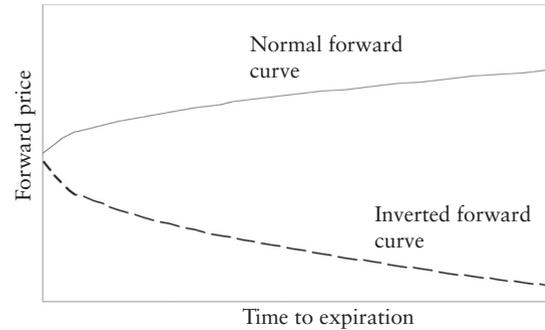

Figure 2 Forward curve: Relation between forward price and its time to expiration. Where time to expiration is 0, forward price equals spot price.

the cost of storage and convenience yield. The zero-coupon yield curve refers to the relation between interest rates and term to maturity.

In terms of swap valuation, the nature of the forward curve is irrelevant as long as the forward prices represent tradable prices. To see this, consider a jeweler (i.e., long hedger) who needs 1,000 troy ounces of gold each quarter over the next two years and wants to lock in his input cost today. One hedging alternative is to buy a strip of forward (or futures) contracts, one corresponding to each desired delivery date. The cost of the gold each quarter will be locked in; however, the cost of the gold will be different each quarter unless the forward curve is a horizontal line. The gold market, however, is typically in contango, so the cost, although certain, will escalate through time. A second alternative is to buy a swap contract that provides for the delivery of 1,000 ounces of gold each quarter, where there is single fixed price for all deliveries.² In the absence of costless arbitrage opportunities, it must be the case that the present value of the deliveries using the forward curve must be the same as the present value of the deliveries using the fixed price of the swap contract, that is,

$$\sum_{i=1}^n f_i e^{-r_i T_i} = \sum_{i=1}^n \bar{f} e^{-r_i T_i} \quad (6)$$

where n is the number of delivery dates, f_i is the price of a forward contract with time to expiration T_i , r_i is the risk-free rate of interest corresponding to time to expiration T_i ,³ and f is the fixed price in the swap agreement.⁴ In an instance where the right-hand side of (6) is greater (less) than the left-hand side, an arbitrageur would buy (sell) the swap and sell (buy) the strip of forward contracts, pocketing the difference. Because such free money opportunities do not exist, (6) must hold as an equality.

Equation (6) can be rearranged to isolate the fixed price of the swap agreement, that is,

$$\bar{f} = \frac{\sum_{i=1}^n f_i e^{-r_i T_i}}{\sum_{i=1}^n e^{-r_i T_i}} = \sum_{i=1}^n f_i \left(\frac{e^{-r_i T_i}}{\sum_{i=1}^n e^{-r_i T_i}} \right) \quad (7)$$

Expressed in this fashion, it becomes obvious that the fixed price of a swap is a weighted average of forward prices, one corresponding to each delivery date.⁵

KEY POINTS

- The net cost of carry is the cost of holding an asset over a period of time. One component of the cost of carry for all assets is the opportunity cost of funds. In order to buy the asset, an investor must pay for it.
- Beyond interest cost, however, carry costs may be positive or negative, depending upon the nature of the underlying asset. If the asset is a physical asset or commodity such as grain, the asset holder must pay storage costs such as warehouse rent and insurance. If the underlying asset is a financial asset or security such as a stock, a bond, or a currency, on the other hand, there are no storage costs. Instead, such assets produce a known income stream in the form of dividend payments or interest receipts, and this income can be used to subsidize the cost of borrowing.

- The interest cost is modeled as a constant continuous rate and the noninterest costs/benefits as either continuous rates or discrete cash flows, depending on the nature of the underlying asset.
- Given the assumption and definition of the cost of carry, pricing equations for forward and futures contracts can be developed. The price of a forward equals the price of a futures and both are equal to the asset price plus net carry costs. This is because if an investor needs an asset on hand at some future date at a price “locked-in” today, the investor can buy a forward contract, buy a futures, or buy the underlying asset and carry it.
- Perfect substitutes must have the same price.
- The relation between the forward curve and the fixed price of a swap is as follows. In the absence of costless arbitrage opportunities, the fixed price is a weighted average of the prices of the corresponding forward contracts, with the weights equal to the discount factor of each flow in relation to the sum of all discount factors.

NOTES

1. Cox, Ingersoll, and Ross (1981) use no-arbitrage arguments to demonstrate the equivalence of forward and futures prices when future interest rates are known. They go on to show, however, that if interest rates are uncertain, the futures price will be greater than or less than the forward price, depending upon whether the correlation between futures price changes and interest rate changes is negative or positive. See also Jarrow and Oldfield (1981).
2. As a practical matter, many swap agreements are cash-settled, so, instead of paying the fixed price per ounce and receiving 1,000 ounces in gold, we will receive in cash 1,000 times the difference between the prevailing (random) spot price of gold each

quarter and the fixed price. If the spot price is greater than the fixed price, we receive a cash payment from our counter-party, and vice versa.

3. Note that we are allowing for the fact that the risk-free rate may be term-specific.
4. The delivery quantity is irrelevant since it is the same on both sides of the equation. That is, equation (6) assumes that one unit is delivered on each delivery date.
5. For illustrations of how to compute the fixed rate of a swap based on the forward curve and the unwind price of swap based on

forward curve, see Chapter 4 in Whaley (2006).

No-Arbitrage Price Relations for Options

ROBERT E. WHALEY, PhD

Valere Blair Potter Professor of Management and Co-Director of the Financial Markets Research Center, Owen Graduate School of Management, Vanderbilt University

Abstract: For derivative instruments, in the absence of costless arbitrage price relations can be developed. In the case of options (calls and puts), there are three types of price relations that can be obtained. The first is the lower bound on the option's price. The second, and perhaps most important, no-arbitrage price relation is the one between the price of a put and the price of a call. This relation is called the put-call parity relation and arises from simultaneous trades in the call, the put, and the asset. The third price relation is the intermarket relation, which is the link between the prices of asset options and the prices of futures options. The price relations exist for European-style and American-style options and under both the continuous rate and discrete flow net cost of carry assumptions. Price relations are important for risk management strategies using options. Option pricing models go beyond these price relations to provide a fair value for an option.

The purpose of this entry is to develop *no-arbitrage price relations* for option contracts assuming that two perfect substitutes have the same price. In the absence of *costless arbitrage* opportunities, options have three types of no-arbitrage price relations—lower bounds, *put-call parity* relations, and intermarket relations. Each type of relation is developed in turn, for both European- and American-style options¹ and under both the continuous rate and discrete flow *net cost of carry* assumptions. Before deriving the no-arbitrage price relations for options, however, we focus on clearly distinguishing between the characteristics of option and forward contracts.

OPTIONS AND FORWARDS

Options differ from forwards in two key respects. First, the net cost of carry of a *forward* contract is zero since it involves no investment outlay. An option, on the other hand, involves investment. An option buyer pays the option premium for the right to buy or sell the underlying asset, and, like the buyer of any other asset, faces carry costs. For an option, however, the only carry cost is interest. Holding an option neither produces income like a dividend-paying stock nor requires storage costs like a commodity (i.e., a physical asset).

The effects of carry costs on the terminal profit functions of forward and option contracts are

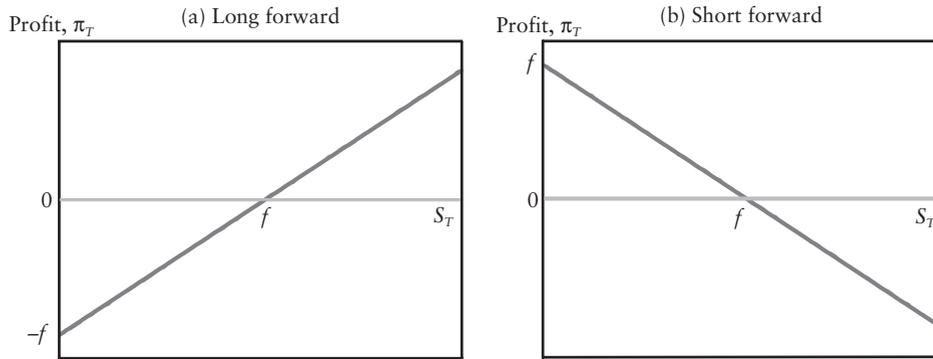

Figure 1 Terminal Profit of Long and Short Forward Positions

shown in Figures 1 through 3. The profit from a long forward position at expiration is

$$\pi_{\text{long forward}, T} = S_T - f \quad (1)$$

where S_T denotes the future price of the asset and f denotes the forward price.

On the other hand, the profit from a long call position is

$$\pi_{\text{long call}, T} = \begin{cases} S_T - X - ce^{rT}, & \text{if } S_T \geq X \\ -ce^{rT}, & \text{if } S_T < X \end{cases} \quad (2)$$

and from a long put position is

$$\pi_{\text{long put}, T} = \begin{cases} -pe^{rT}, & \text{if } S_T \geq X \\ X - S_T - pe^{rT}, & \text{if } S_T < X \end{cases} \quad (3)$$

where c and p are the prices of a European-style call and put, respectively; X is the exercise

price or strike price of the option. The opportunity cost of funds (i.e., the risk-free rate of interest) is denoted by r . Note that the profit functions for the long call and the long put (2) and (3) reflect the fact that the initial option premiums, c and p , are carried forward until the option's expiration at the risk-free interest rate. We have lost the opportunity cost of the funds we tied up in buying the option. Conversely, short call and short put positions (i.e., $\pi_{\text{short call}, T} = -\pi_{\text{long call}, T}$ and $\pi_{\text{short put}, T} = -\pi_{\text{long put}, T}$) reflect the fact that the option seller receives the premium payment and invests the cash at the risk-free interest rate. The profit function of a long forward position (1) has no interest component since the forward price is a promised payment on day T rather than a cash outlay today.

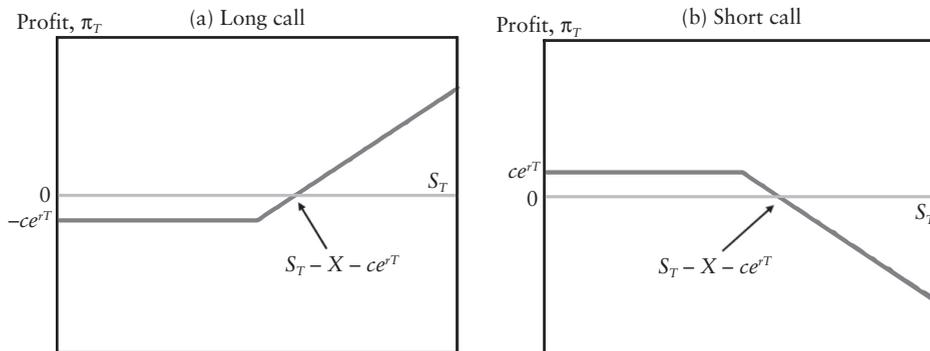

Figure 2 Terminal Profit of Long and Short Call Positions

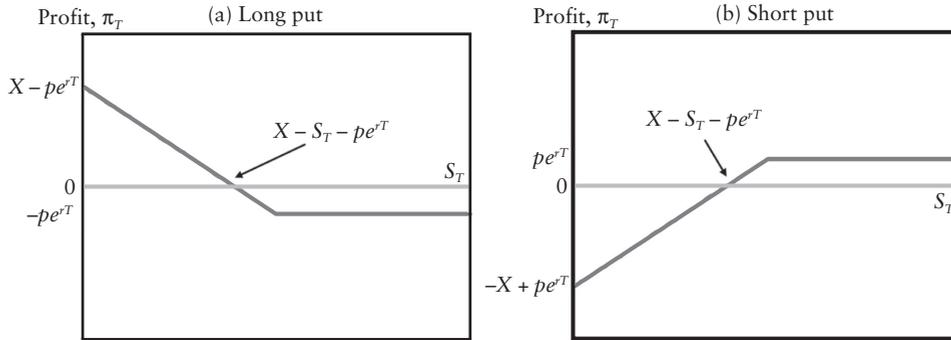

Figure 3 Terminal Profit of Long and Short Put Positions

The second key difference between forwards and options is that the buyer of a forward is obliged to buy the underlying asset at expiration, independent of whether or not the terminal asset price is greater than or less than the initial forward price. The buyer of an option, on the other hand, is not obliged to buy or sell the underlying asset, but will do so only when it is profitable. The profit function for the long call position (2), for example, shows that the option is exercised only when $S_T \geq X$. If $S_T < X$, the call option buyer chooses not to exercise, forfeiting only his original investment plus carry costs, ce^{rT} . The limited liability feature of the long call and long put positions are illustrated in Figures 2a and 3a, respectively. In the interest of completeness, the short positions in the respective instruments are illustrated in Figures 1b through 3b.

The profit functions of the *call* and the *put* show a certain complementarity to the profit function of a forward. Suppose we buy a call and sell a put at the same exercise price. The profit function for the overall position is

$$\begin{aligned} \pi_{c,T} - \pi_{p,T} &= \begin{cases} S_T - X - ce^{rT} + pe^{rT} & \text{if } S_T \geq X \\ S_T - X - ce^{rT} - pe^{rT} & \text{if } S_T < X \end{cases} \\ &= S_T - X - ce^{rT} - pe^{rT} \end{aligned}$$

Now, suppose that we chose the exercise price of the options such that $X = f - ce^{rT} + pe^{rT}$. The profit functions of the option portfolio and the long forward position will be exactly the same. If we buy the option portfolio and sell the

forward contract, the terminal value of the overall position must be 0. In the absence of costless arbitrage opportunities, the current value of the position must also be equal to 0, and, therefore, the call and put prices must be equal. Buying the call and selling the put (with the exercise price defined as above) is a perfect substitute for buying a forward. Viewed in this way, we can construct virtually any derivatives contract from any of the following pairs of basic instruments: (1) a forward and a call, (2) a forward and a put, and (3) a call and a put.

CONTINUOUS RATES

The *net cost of carry* refers to the difference between the costs and the benefits of holding an asset. One carry cost common to all assets is the opportunity cost of funds. We assume this cost is incurred at the risk-free rate of interest. Beyond interest cost, however, carry costs vary depending upon the nature of the asset. For a physical asset or commodity, we incur storage costs (e.g., rent and insurance). At the same time, certain benefits may accrue. By storing wheat we may avoid some costs of possible running out of our regular inventory before two months are up and having to pay extra for emergency deliveries. This is called *convenience yield*. Thus, the net cost of carry for a commodity equals interest cost plus storage costs less convenience yield.

Table 1 Arbitrage Portfolio Trades Supporting Lower Price Bound of European-Style Call Option Where the Underlying Asset Has a Continuous Net Carry Rate, $c \geq Se^{-iT} - Xe^{-rT}$

Trades	Initial Investment	Value on Day T	
		$S_T < X$	$S_T \geq X$
Sell asset	Se^{-iT}	$-\tilde{S}_T$	$-\tilde{S}_T$
Buy call option	$-c$	0	$-\tilde{S}_T - X$
Buy risk-free bonds	$-Xe^{-rT}$	X	X
Net portfolio value	$Se^{-iT} - Xe^{-rT} - c$	$X - \tilde{S}_T$	0

For a financial asset or security such as a stock or a bond, the carry costs/benefits are different. While borrowing costs remain, securities do not require storage costs and do not have convenience yields. What they do have, however, is income (yield) that accrues in the form of quarterly cash dividends or semiannual coupon payments. Thus, the net cost of carry for a security is equal to the cost of funds reduced by income. Carry costs and benefits are modeled either as continuous rates or as discrete flows. Some costs/benefits such as the cost of funds (i.e., the risk-free interest rate) are best modeled as continuous rates.

Under the continuous rate assumption, both interest cost and noninterest costs/benefits are modeled as continuous rates. Under the discrete flow assumption, interest cost is modeled as a continuous rate but noninterest costs/benefits are modeled as discrete cash flows. This section relies on the continuous rate assumption. The interest carry cost rate is represented by the notation r , and the noninterest carry benefit/cost rate is i . If the asset holder receives income from holding the asset such as the dividend yield on a stock portfolio or interest on a foreign currency investment, the income rate is positive (i.e., $i > 0$). If the asset holder pays costs in addition to interest in order to hold the asset (e.g., storage costs of holding a physical commodity), the income rate is negative (i.e., $i < 0$). Where $i = 0$, the only cost of carry is interest. As noted earlier in this section, the net cost of carry of an option is simply the interest rate.

Lower Price Bound of European-Style Call

Under the continuous rate assumption, the lower price bound of a European-style call option is

$$c \geq \max(0, Se^{-iT} - Xe^{-rT}) \quad (4)$$

The reason that the call price must be greater or equal to 0 is obvious—we do not have to be paid to take on a privilege. The reason the call price must exceed $Se^{-iT} - Xe^{-rT}$ is less obvious and is derived by means of an arbitrage portfolio. Suppose we form a portfolio by selling e^{-iT} units of the underlying asset² and buying a European-style call. In addition, to make sure that we have enough cash on hand to exercise the call at expiration, we buy Xe^{-rT} in risk-free bonds. The initial investment and terminal values of these positions are shown in Table 1. On day T , the net terminal value of the portfolio depends on whether the asset price is above or below the exercise price. If the asset price is less than the exercise price (i.e., $S_T < X$), we let the call expire worthless. We then use the risk-free bonds to buy one unit of the asset to cover the short sale obligation. What remains is $X - \tilde{S}_T$, which we know is greater than 0. If the asset price is greater than or equal to the exercise price (i.e., $S_T \geq X$), we exercise the call. This requires a cash payment of X . Fortunately we have exactly that amount on hand in the form of risk-free bonds. The unit of the asset that we receive upon exercising the call is used to retire

the short sale obligation. In this case, the net terminal value is certain to be 0.

What are the implications of this strategy? Well, we have formed a portfolio that is certain to have a terminal value of at least 0. In the absence of costless arbitrage opportunities, this implies that the greatest initial value is 0. More simply, we cannot reasonably expect to collect money at the outset without risk of loss. In the absence of costless arbitrage opportunities, $Se^{-iT} - Xe^{-rT} - c \leq 0$. Hence, a lower price bound for the European-style call is $c \geq Se^{-iT} - Xe^{-rT}$.³

In general, the lower price bound of an option is called its intrinsic value, and the difference between the option's market value (price)⁴ and its intrinsic value is called its time value. Thus a European-style call has an intrinsic value of $\max(0, Se^{-iT} - Xe^{-rT})$ and a time value of $c - \max(0, Se^{-iT} - Xe^{-rT})$. This entry deals with identifying intrinsic values by virtue of no-arbitrage arguments. Option pricing models uncover the determinants of time value.

To illustrate, suppose a three-month European-style call option written on a stock index portfolio has an exercise price of 70 and a market price of 4.25. Suppose also the current index level is 75, the portfolio's dividend yield rate is 4%, and the risk-free rate of interest is 5%. Is a costless arbitrage profit possible?

To test for the possibility of a costless arbitrage profit, substitute the problem parameters into the lower price bound (4), that is,

$$4.25 < \max[0, 75e^{-0.04(3/12)} - 70e^{-0.05(3/12)}] = 5.12$$

Since the lower bound relation is violated, a costless arbitrage profit of at least $5.12 - 4.25 = 0.87$ is possible. Since the violation may result from either the call being underpriced or the asset being overpriced, the arbitrage requires buying the call and selling the asset.⁵ The appropriate arbitrage trades are provided in Table 1. Substituting the prices and rates,

Trades	Initial Investment	Value at Time T	
		$ST < 70$	$ST \geq 70$
Sell index portfolio	74.25	$-\tilde{S}_T$	$-\tilde{S}_T$
Buy call option	-4.25	0	$\tilde{S}_T - 70$
Buy risk-free bonds	-69.13	70	70
Net portfolio value	0.87	$70 - \tilde{S}_T$	0

In examining the net portfolio value, note that you (a) earn an immediate profit of 0.87, and (b) have the potential of earning even more if the index level is below 70 at the option's expiration. If prices in the market were actually configured at such levels, you should expect that buying pressure on the call and selling pressure on the index portfolio would very quickly return the market to equilibrium. In the absence of costless arbitrage opportunities, $c \geq Se^{-iT} - Xe^{-rT}$.

Lower Price Bound of American-Style Call

American-style options are like European-style options except that they can be exercised at any time up to and including the expiration day. Since this additional right cannot have a negative value, the relation between the prices of American-style and European-style call options is

$$C \geq c \tag{5}$$

where the uppercase C represents the price of an American-style call option with the same exercise price and time to expiration and on the same underlying asset as the European-style call. The lower price bound of an American-style call option is

$$C \geq \max(0, Se^{-it} - Xe^{-rt}, S - X) \tag{6}$$

This is the same as the lower price bound of the European-style call (4), except that the term $S - X$ is added within the maximum value operator on the right-hand side. The reason is, of course, that the American-style call cannot sell for less than its immediate early exercise proceeds, $S - X$. If $C < S - X$, a costless arbitrage profit

of $S - X - C$ can be earned by simultaneously buying the call (and exercising it) and selling the asset.

As an illustration, suppose a three-month American-style call option written on a stock index portfolio has an exercise price of 70 and a market price of 4.25. Suppose also the current index level is 75, the portfolio's dividend yield rate is 4%, and the risk-free rate of interest is 5%. Is a costless arbitrage profit possible?

To test for the possibility of a costless arbitrage profit, substitute the problem information into (6), that is,

$$\begin{aligned} 4.25 &< \max[0, 75e^{-0.04(3/12)} \\ &\quad - 70e^{-0.05(3/12)}, 75 - 70] \\ &= \max(0, 5.12, 5) = 5.12 \end{aligned}$$

At the current call price of 4.25, two types of arbitrage are possible. A costless arbitrage profit of $5.00 - 4.25 = 0.75$ is possible simply by buying the call, exercising it, and selling the asset. The amount of this arbitrage profit, however, is less than the arbitrage profit of at least $5.12 - 4.25 = 0.87$ that can be earned by buying the call, selling the asset, buying risk-free bonds, and holding the portfolio until the call's expiration, as was shown in the previous arbitrage table. Under this second alternative, you earn an immediate profit of 0.87, and have the potential of earning even more if the asset price is below 70 at the option's expiration.

Early Exercise of American-Style Call Options

The structure of the lower price bound of the American-style call (6) can be used to provide important insight regarding the possibility of *early exercise*. The second term in the squared brackets, $Se^{-iT} - Xe^{-rT}$, is the minimum price at which the call can be sold in the marketplace.⁶ The third term is the value of the American-style if it is exercised immediately. If the value

of the second term is greater than the third term (for a certain set of call options), the call's price in the marketplace will be always exceed its exercise proceeds so it will never be optimal to exercise the call early.

To identify this set of calls, we must examine the conditions under which the relation

$$Se^{-iT} - Xe^{-rT} > S - X$$

holds. The job is easier if we rearrange the relation to read

$$S(e^{-iT} - 1) > -X(1 - e^{-rT}) \quad (7)$$

Since the risk-free interest rate is positive, the expression of the right-hand side is negative. If the left-hand side is positive or zero, the call option holder can always get more by selling his option in the marketplace than by exercising it; so early exercise will never be optimal and the value of the American-style call is equal to the value of the European-style call, $C = c$. This condition is met for calls whose underlying asset has a negative or zero noninterest carry rate, $i \leq 0$.

The intuition for this result can be broken down into two components—interest cost, r , and noninterest benefit (i.e., $i > 0$) or cost (i.e., $i < 0$). With respect to interest cost, recognize that exercising the call today requires that we pay X today. If we defer exercise until the call's expiration, on the other hand, we have the opportunity to earn interest (i.e., our liability is only the present value of the exercise cost, Xe^{-rT}). So, holding other factors constant, we always have an incentive to defer exercise.⁷ With respect to the noninterest costs, recall that assets with $i < 0$ are typically physical assets that require storage. If we exercise a call written on such an asset, we must take delivery, whereupon we immediately begin to incur storage costs. If we defer exercise, on the other hand, and continue to hold the claim on the asset rather than the asset itself, we avoid paying storage costs. Thus, where $i < 0$, there are two reasons not to exercise early. But even if storage

costs are zero (i.e., with $i = 0$), condition (7) holds since the interest cost incentive remains.

For American-style call options on assets with $i > 0$ (e.g., stock index portfolio with a nonzero dividend yield and foreign currencies with a nonzero foreign interest rate), on the other hand, early exercise may be optimal. The intuition is that, while there remains the incentive to defer exercise and earn interest on the exercise price, deferring exercise means forfeiting the income on the underlying asset (e.g., the dividend yield on a stock index portfolio). The only way to capture this income is by exercising the call and taking delivery of the asset. For American-style call options on assets with $i > 0$, early exercise may be optimal and, therefore, $C > c$.

Lower Price Bound of European-Style Put

The lower price bound of a European-style put option is

$$p \geq \max(0, Xe^{-rT} - Se^{-iT}) \tag{8}$$

Again, the reason that the option price must be greater or equal to 0 is obvious—we do not have to be paid to take on a privilege. The reason the put price must exceed the bound, $Xe^{-rT} - Se^{-iT}$, is given by the arbitrage trade portfolio in Table 2. If we buy e^{-iT} units of the asset and a put, and sell Xe^{-rT} risk-free bonds, the net terminal value of the portfolio is certain to be greater than or equal to 0. If the asset price is less than or equal to the exercise price at the

option’s expiration (i.e., $S_T \leq X$), we will exercise the put, delivering the asset and receiving X in cash. We will then use the exercise proceeds X to cover our risk-free borrowing obligation. In the event the asset price is greater than the exercise price (i.e., $S_T > X$), we will consider the put expire worthless. We still need to cover our risk-free borrowing, which we do by selling the asset. After repaying our debt, we have $\tilde{S}_T - X$ remaining.

For example, a three-month European-style put option written on a stock index portfolio has an exercise price of 70 and a market price of 8.80. Suppose also the current index level is 61, the portfolio’s dividend yield rate is 4%, and the risk-free rate of interest is 5%. Is a costless arbitrage profit possible?

To test for the possibility of a costless arbitrage profit, substitute the problem parameters into the lower price bound (8),

$$8.80 > \max[0, 70e^{-0.05(3/12)} - 61e^{-0.04(3/12)}] = 8.74$$

At the current price of 8.80, the no-arbitrage condition (8) holds, so no costless arbitrage opportunity exists.

Lower Price Bound for American-Style Put

An American-style put has an early exercise privilege, which means that the relation between the prices of American-style and European-style put options is

$$P \geq p \tag{9}$$

Table 2 Arbitrage Portfolio Trades Supporting Lower Price Bound of European-Style Put Option Where the Underlying Asset Has a Continuous Net Carry Rate, $p \geq Xe^{-rT} - Se^{-iT}$

Trades	Initial Investment	Value on Day T	
		$S_T < X$	$S_T \geq X$
Sell asset	$-Se^{-iT}$	\tilde{S}_T	\tilde{S}_T
Buy call option	$-p$	$X - \tilde{S}_T$	0
Buy risk-free bonds	Xe^{-rT}	$-X$	$-X$
Net portfolio value	$Xe^{-rT} - Se^{-iT} - p$	0	$\tilde{S}_T - X$

where uppercase P represents the price of an American-style put option with the same exercise price, time to expiration, and underlying asset as the European-style put. The lower price bound of an American-style put option is

$$p \geq \max(0, Xe^{-rT} - Se^{-iT}, X - S) \quad (10)$$

This is the same as the lower price bound of the European-style put (8), except that, because the American-style put may be exercised at any time including now, the exercise proceeds, $X - S$, is added within the maximum value operator on the right-hand side. If $P < X - S$, a costless arbitrage profit of $X - S - P$ can be earned by simultaneously buying the put (and exercising it) and buying the asset.

To illustrate, assume that a three-month American-style put option written on a stock index portfolio has an exercise price of 70 and a market price of 8.80. Suppose also the current index level is 61, the portfolio's dividend yield rate is 4%, and the risk-free rate of interest is 5%. Is a costless arbitrage profit possible?

To test for the possibility of a costless arbitrage profit, substitute the problem information into (10), that is,

$$\begin{aligned} 8.80 &< \max[0, 70e^{-0.05(3/12)} \\ &\quad - 61e^{-0.04(3/12)}, 70 - 61] \\ &= \max(0, 8.74, 9.00) = 9.00 \end{aligned}$$

At the current price of 8.80, the no-arbitrage relation (10) is violated, indicating the presence of a costless arbitrage opportunity. Since it is the early exercise condition (third term) on the right-hand side that is violated, you should buy the put (and exercise it) and buy the index portfolio. You would pay 8.80 for the put and 61 for the index portfolio, and receive 70 when you deliver the index portfolio upon exercising the put. The amount of the arbitrage profit is 0.20 and is earned immediately.

Early Exercise of American-Style Put Options

In the case of an American-style call, we found that if the underlying asset had carry costs and above interest (e.g., storage), the call option holder would never (rationally) exercise early. In the case of an American-style put, no comparable condition exists.⁸ There is always some prospect of early exercise, so the American-style put is always worth more than the European-style put, that is, $P > p$. The intuition is straightforward. Suppose, for whatever reason, the asset price falls to 0. The put option holder should exercise immediately. There is no chance that the asset price will fall further, so delaying exercise means forfeiting the interest income that can be earned on the exercise proceeds of the put, X . The interest-induced, early-exercise incentive works in exactly the opposite way for the put than it did for the call. For the put, we want to exercise early to get the cash and let it begin to earn interest. For the call, we want to defer exercise and let the cash continue to earn interest.

Put-Call Parity for European-Style Options

Perhaps the most important no-arbitrage price relation for options is put-call parity.⁹ The put-call parity price relation arises from the simultaneous trades in the call, the put, and the asset. Put-call parity for European-style options is given by

$$c - p = Se^{-iT} - Xe^{-rT} \quad (11)$$

The composition of the put-call parity arbitrage portfolio is given in Table 3. A portfolio that consists of a long position of e^{-iT} units of the asset, a long put, a short call, and a short position of Xe^{-rT} in risk-free bonds is certain to have a net terminal value of 0. If the terminal asset price is less than or equal to the exercise price of the options (i.e., $S_T \leq X$), we exercise the put and deliver the asset. The cash proceeds

Table 3 Arbitrage Portfolio Trades for European-Style Put-Call Parity Where the Underlying Asset Has a Continuous Net Carry Rate, $c - p = Se^{-iT} - Xe^{-rT}$

Trades	Initial Investment	Value at Time T	
		$S_T < X$	$S_T \geq X$
Buy asset	$-Se^{-iT}$	\tilde{S}_T	\tilde{S}_T
Buy put option	$-p$	$X - \tilde{S}_T$	0
Sell call option	c	0	$-(\tilde{S}_T - X)$
Sell risk-free bonds	Xe^{-rT}	$-X$	$-X$
Net portfolio value	$Xe^{-rT} - Se^{-iT} - p + c$	0	0

from exercise are used to repay our debt. The call option is out-of-the-money, so the call option holder will let it expire worthless. On the other hand, if the terminal asset price exceeds the exercise price (i.e., $S_T > X$), we will let our put expire worthless. The call option holder will exercise, requiring that we deliver a unit of the asset, which we just happen to have.¹⁰ The call option holder pays us X , which we use to retire our risk-free borrowings. Since the net terminal portfolio value is zero, the cost of entering into such a portfolio today must also be 0, otherwise costless arbitrage would be possible. If the initial investment is 0, the put-call parity relation (11) holds.

The set of arbitrage trades spelled out in Table 3 (i.e., buy the asset, buy the put, sell the call, and sell risk-free bonds) is called a conversion. If all of the trades are reversed (i.e., sell the asset, sell the put, buy the call, and buy risk-free bonds), it is called a reverse conversion. These names arise from the fact that we can create any position in the asset, options, or risk-free bonds by trading (or converting) the remaining secu-

rities, in the same manner we used a call and a put to create a forward contract at the beginning of the entry. Table 4 provides a complete list of the conversions that are possible using the put-call parity relation for European-style options. The first row says that buying the asset, buying a put, and selling a call is equivalent to buying risk-free bonds. We can check this by creating an arbitrage trade table, or by simply working through it mentally. If the asset price is less than the exercise price at expiration, we will exercise our put and sell the asset. If the asset price is greater than the exercise price, the call option holder will exercise, requiring that we deliver the asset. In both cases, we are certain to have X in cash when all is said and done. This is the same as the amount we would have had if we bought risk-free bonds.

Let's see how put-call parity is applied for European-style options. Suppose that a three-month call and put with an exercise price of 70 have prices of 5.00 and 4.50, respectively. Suppose also that the current level of the index

Table 4 Perfect Substitutes Implied by European-Style Put-Call Parity

Position 1		Position 2
Buy asset/buy put/sell call	=	Buy risk-free bonds (lend)
Buy asset/buy put/sell risk-free bonds	=	Buy call
Sell asset/buy call/buy risk-free bonds	=	Buy put
Sell put/buy call/buy risk-free bonds	=	Buy asset
Sell asset/sell put/buy call	=	Sell risk-free bonds (borrow)
Sell asset/sell put/buy risk-free bonds	=	Sell call
Buy asset/sell call/sell risk-free bonds	=	Sell put
Buy put/sell call/sell risk-free bonds	=	Sell asset

portfolio underlying the options is 70, the index portfolio has a dividend yield rate of 3%, and the risk-free rate of interest is 5%. Is a costless arbitrage profit possible?

To test for the possibility of a costless arbitrage profit, substitute the problem parameters into the put-call parity relation (11),

$$5.00 - 4.50 = 0.50 > 70e^{-0.03(3/12)} - 70e^{-0.05(3/12)} = 0.34$$

Since the equation does not hold, a costless arbitrage profit is possible. Since the violation may result from either the call being overpriced, the put being underpriced, or the asset being underpriced, the arbitrage will require all three trades: selling the call, buying the put, and buying the asset. Using the trades as set out in Table 3, we get:

Trades	Initial Investment	Value at Time T	
		$S_T < 70$	$S_T \geq 70$
Buy asset	-69.48	\tilde{S}_T	\tilde{S}_T
Buy put option	-4.50	$\tilde{S}_T - 70$	0
Sell call option	5.00	0	$-(\tilde{S}_T - 70)$
Sell risk-free bonds	69.13	-70	-70
Net portfolio value	0.16	0	0

By forming this portfolio, we generate a costless arbitrage profit of 0.16. The buying pressure on the index portfolio and the put will cause their prices to rise, and the selling pressure on the call will cause its price to fall. The arbitrage trading will stop when the initial value investment column sums to zero (i.e., the costless ar-

bitrage opportunity ceases to exist), or where $c - p = Se^{-iT} - Xe^{-rT}$.

Put-Call Parity for American-Style Options

The early exercise feature of American-style options complicates the put-call parity relation. The nature of the relation depends on the level of noninterest costs/benefits, i . Specifically, the put-call parity relations are

$$S - X \leq C - P \leq Se^{-iT} - Xe^{-rT} \quad \text{if } i = 0 \quad (12a)$$

and

$$Se^{-iT} - X \leq C - P \leq S - Xe^{-rT} \quad \text{if } i > 0 \quad (12b)$$

Each inequality in (12a) and in (12b) has a separate set of arbitrage trades. To illustrate, consider (12b), the case in which the asset pays some form of income, say, a stock index portfolio with a constant dividend yield rate, or a foreign currency with a constant foreign risk-free rate of interest. To establish the left-hand side inequality of (12b), consider the arbitrage portfolio trades in Table 5. To generate the table entries, assume the left-hand side inequality of (12b) is reversed. This means the asset price is overpriced, the put is overpriced, and/or the call is underpriced. Thus, the arbitrage portfolio must account for all three possibilities. We should sell the asset, sell the put, buy the call, and buy some risk-free bonds. At the options' expiration, the portfolio is certain to have

Table 5 Arbitrage Portfolio Trades Supporting American-Style Put-Call Parity Where the Underlying Asset Has a Continuous Net Carry Rate, $Se^{-iT} - X < C - P$

Trades	Initial Investment	Early Exercise at t	Value on Day T	
			$S_T < X$	$S_T \geq X$
Sell asset	$-Se^{-iT}$	$-\tilde{S}_t e^{-i(T-t)}$	$-\tilde{S}_T$	$-\tilde{S}_T$
Sell put option	P	$-(X - \tilde{S}_t)$	$-(X - \tilde{S}_T)$	0
Buy call option	$-C$	$-\tilde{C}_t$	0	$\tilde{S}_T - X$
Buy risk-free bonds	$-X$	Xe^{rt}	Xe^{rT}	Xe^{rT}
Net portfolio value	$Se^{-iT} + P - C - X$	$\tilde{S}_t[1 - e^{-i(T-t)}] + \tilde{C}_t + X(e^{rT} - 1)$	$X(e^{rT} - 1)$	$X(e^{rT} - 1)$

positive value $X(e^{rT} - 1)$. If $S_T < X$, the put option holder exercises, requiring that we pay X in return for a unit of the underlying asset. We pay the exercise price using a portion of our risk-free bonds, and use the delivered asset to cover our short position. On the other hand, if $S_T \geq X$, we exercise the call and receive the asset. The asset delivered on the call is used to cover the short position. We use some of the risk-free bonds to pay for the exercise price of the call.

The early exercise feature of the American-style options requires that we consider one other contingency within the arbitrage table, that is, what happens if the put option holder decides to exercise early at some arbitrary time t between now and expiration. Looking at Table 5, we see that our obligation should the put be exercised early is $-(X - \tilde{S}_t)$. But since we have Xe^{rt} in risk-free bonds, we have more than enough to cover the payment of X to the put option holder. In return, we receive \tilde{S}_t , which is more than enough to cover our short asset position in the asset that has value $-\tilde{S}_t e^{-i(T-t)}$. In addition, we have a long position in the call with value \tilde{C}_t . Because the net portfolio value is positive at expiration and also in the event the put is exercised early, the initial investment must be negative (since if it were zero or positive, there would be a certain arbitrage). And, if $Se^{-iT} - X - C + P < 0$, then $Se^{-iT} - X < C + P$.

To establish the right-hand side inequality of (12b), consider the arbitrage portfolio trades in Table 6. To generate the table entries, again assume the right-hand side inequality of (9b)

is reversed. This means the asset price is underpriced, the put is underpriced, and/or the call is overpriced. The arbitrage portfolio trades must account for all possibilities. We should buy the asset, buy the put, sell the call, and sell some risk-free bonds. At the options' expiration, the portfolio is certain to have positive value $\tilde{S}_T(e^{iT} - 1)$. If $S_T < X$, we exercise the put and sell the asset. The long asset position has a value $\tilde{S}_T e^{iT}$, which is more than enough to pay for the unit of the asset owed on the put. The cash received from exercising the put is used to cover our risk-free bond obligation. On the other hand, if $S_T \geq X$, the call option holder exercises, implying that we receive X in return for delivering one unit of the asset. We use the call received from the call option holder to retire the risk-free bond position. The value of our asset position, $\tilde{S}_T e^{iT}$, is more than we need to deliver on the put.

The early exercise feature of the American-style call must also be considered, that is, what happens if the call option holder decides to exercise early on day t ? Looking at Table 6, we see that the call exercise obligation is $-(\tilde{S}_t - X)$. But, if we receive X , that is more than enough to cover the balance of $-Xe^{-r(T-t)}$ in risk-free bonds. We must pay \tilde{S}_t , but we have more than one unit of the asset, that is, $\tilde{S}_t e^{i(T-t)}$. In addition, we have a long position in the put with value \tilde{P}_t . Since the net portfolio value is positive at expiration and in the event the call is exercised early, the initial investment must be negative. And, if $-S + Xe^{-rT} + C - P < 0$, $C - P < S - Xe^{-rT}$.

Table 6 Arbitrage Portfolio Trades Supporting American-Style Put-Call Parity Where the Underlying Asset Has a Continuous Net Carry Rate, $C - P < S - Xe^{-rT}$

Trades	Initial Investment	Early Exercise at t	Value on Day T	
			$S_T < X$	$S_T \geq X$
Buy asset	$-S$	$\tilde{S}_t e^{iT}$	$\tilde{S}_T e^{iT}$	$\tilde{S}_T e^{iT}$
Buy put option	$-P$	\tilde{P}_t	$X - \tilde{S}_T$	0
Sell call option	C	$-(\tilde{S}_t - X)$	0	$-(\tilde{S}_T - X)$
Sell risk-free bonds	Xe^{rt}	$-Xe^{-r(T-t)}$	$-X$	$-X$
Net portfolio value	$-S - P + Xe^{rT} + C$	$\tilde{S}_t(e^{-it} - 1) + \tilde{P}_t + X[1 - e^{-r(T-t)}]$	$\tilde{S}_T(e^{iT} - 1)$	$\tilde{S}_T(e^{iT} - 1)$

Table 7 No-Arbitrage Price Relations For European- and American-Style Options Where the Underlying Asset Has a Continuous Net Carry Rate

Description	European-Style Options	American-Style Options
Lower price bound for call	$c \geq \max(0, Se^{-iT} - Xe^{-rT})$	$C \geq \max(0, Se^{-iT} - Xe^{-rT}, S - X)$
Lower price bound for put	$p \geq \max(0, Xe^{-rT} - Se^{-iT})$	$P \geq \max[0, Xe^{-rT} - Se^{-iT}, X - S]$
Put-call parity relation	$c - p = Se^{-iT} - Xe^{-rT}$	$S - X < C - P < Se^{-iT} - Xe^{-rT}, \text{ if } i \leq 0$ $Se^{-iT} - X < C - P < S - Xe^{-rT}, \text{ if } i > 0$

Summary

This completes the derivations of no-arbitrage price relations for European-style and American-style options on assets with a continuous net carry rate. For convenience, a summary of the no-arbitrage relations is provided in Table 7.

DISCRETE FLOWS

With the no-arbitrage price relations for an underlying asset with a continuous carry cost rate in hand, the focus now turns to developing the same set of relations for an asset that has interest cost modeled as a continuous rate but noninterest costs/benefits modeled as a discrete flow. If the noninterest flow is income such as in the case of a cash dividend payment on a share of stock or a coupon payment on a bond, the income is represented as a positive value, that is, $I_t > 0$. If the flow is a cost such as, say, warehouse rent from storing an inventory of wheat, the income is represented as a negative value, that is, $I_t < 0$. Again, since this book deals primarily with financial assets, most of the illustrations will have I_t discussed as being a positive value. Although I_t represents a cash payment on any

type of asset, we will call I_t a dividend payment throughout this section for expositional convenience.

Lower Price Bound of European-Style Call

The lower price bound of a European-style call option on an asset that makes a single, discrete cash dividend payment during the option's life is

$$c \geq \max(0, S - I_t e^{-rt} - Xe^{-rT}) \quad (13)$$

In this relation, $I_t e^{-rt}$ is the present value of the promised dividend to be received at time t , where $t < T$. The arbitrage trading strategy that supports (13) is: sell the asset, buy a call, and buy risk-free bonds. The initial investment and terminal values are shown in Table 8. The first row in the table represents the short asset position. Today, we collect S , and, at the option's expiration, the short position must be covered at a cost of \tilde{S}_T . Shorting an asset, however, requires that we pay any dividends on the underlying asset. If we are short a stock and the stock pays a dividend, for example, we are obliged to pay the dividend out of our own pocket. Since the dividend is made during the option's life

Table 8 Arbitrage Portfolio Trades Supporting Lower Price Bound of European-Style Call Option Where the Underlying Asset Pays a Discrete Cash Dividend, $C - P < S - Xe^{-rT}$

Trades	Initial Investment	Cash Flow at t	Value on Day T	
			$S_T < X$	$S_T \geq X$
Buy asset	S	$-I_t$	$-\tilde{S}_T$	$-\tilde{S}_T$
Buy call option	$-c$		0	$\tilde{S}_T - X$
Buy risk-free bonds	$-Xe^{-rT} - I_t e^{-rt}$	I_t	X	X
Net portfolio value	$S - I_t e^{-rt} - Xe^{-rT} - c$	0	$X - \tilde{S}_T$	0

(i.e., $t < T$), the first row has a cash outflow of $-I_t$ paid on day t . The second row shows the long call position. On day t , the call is worth nothing if $S_t < X$ and $S_t - X$ if $S_t \geq X$. Finally, we buy some risk-free bonds. The amount necessary must be sufficient to cover the payment of the exercise price, X , on day T and the payment of the cash dividend, I_t , on day t , that is, $-Xe^{-rT} - I_t e^{-rt}$. Since the portfolio is certain to have a nonnegative net value on day t , the net portfolio value today must be less than or equal to 0, which implies $c \geq S - I_t e^{-rt} - Xe^{-rT}$.

Lower Price Bound of American-Style Call

A discrete cash dividend payment on the underlying asset affects the early exercise behavior of American-style call options differently than in the continuous carry rate case. In the case of an American-style call written on a stock, it may be optimal to exercise either just prior to the ex-dividend date (when the stock price falls by I_t) or at expiration. Early exercise between today and the ex-dividend instant and between the ex-dividend instant and expiration are not optimal because the call is worth more alive than dead.¹¹ The lower price bound of an American-style call is therefore the lower bound of a call expiring at the ex-dividend instant, $\max(0, S - Xe^{-rt})$, and the lower bound of the call expiring at expiration, $\max(0, S - I_t e^{-rt} - Xe^{-rT})$. Combining these two results,

$$c \geq \max(0, S - Xe^{-rt}, S - I_t e^{-rt} - Xe^{-rT}) \quad (14)$$

Early Exercise of American-Style Call Options

The last two terms on the right-hand side of (14) provide important guidance in deciding whether to exercise the American call option early, just prior to the ex-date. The second term in the parentheses is the present value of the early proceeds of the call. If this amount is less than the lower price bound of the call that ex-

pires normally, that is, if

$$S - Xe^{-rt} < S - I_t e^{-rt} - Xe^{-rT}$$

an American-style call will not be exercised early. To understand why, rewrite the expression as

$$I_t < X[1 - e^{-r(T-t)}] \quad (15)$$

The American-style call will not be exercised early if the cash flow (e.g., dividend or coupon payment) captured by exercising prior to the ex-date is less than the interest implicitly earned by deferring exercise from the ex-date until expiration.

The logic underlying the relation (15) also applies to the case where there are multiple known dividends paid during the call option's life. Take a stock option, for example. If the i th dividend is less than the present value of the interest income that can be implicitly earned as a result of deferring the payment of the exercise price until the next dividend payment, that is, if

$$I_i < X[1 - e^{-r(t_{i+1}-t_i)}] \quad (16)$$

exercising just prior to the i th dividend payment will not be optimal. This relation proves useful for simplifying the valuation of long-term stock options. The following example shows that dividend-induced early exercise on a long-term American-style call is most likely to occur just prior to the last dividend payment during the option's life.

Let's identify whether an American-style call option with an exercise price of 50 and one year remaining to expiration may be exercised early just prior to any of the dividend payments. Assume that the stock pays a quarterly dividend of 0.50 in 70 days, 161 days, 252 days, and 343 days. Assume the risk-free rate of interest is 5%.

Whether or not the call may be exercised early depends on the amount of the dividend payment in relation to the present value of the

interest income implicitly received by deferring the payment of the exercise price. For the first dividend, compute the values in expression (16) and find

$$0.50 < 50[1 - e^{-0.05(161/365-70/365)}] = 0.6194$$

Hence, the call will not optimally be exercised just prior to the first dividend payment. The same is true for the second and third dividend payments, as shown in the table below.

Quarter	Cash Dividend	Days to Dividend Payment	Years to Dividend Payment	PV of Interest Income
1	0.50	70	0.1918	0.6194
2	0.50	161	0.4411	0.6194
3	0.50	252	0.6904	0.6194
4	0.50	343	0.9397	0.1505

For the last dividend payment in 353 days, condition (13) is violated, that is,

$$0.50 > 50[1 - e^{-0.05(365-343)/365}] = 0.1505$$

This implies that exercise just prior to the last dividend payment during this option's life may be optimal.

Lower Price Bound of European-Style Put

The lower price bound for the European-style put option is

$$p \geq \max(0, Xe^{-rT} - S + I_t e^{-rt}) \quad (17)$$

Again, the asset price is reduced by the present value of the promised cash dividend on the asset. Unlike the call, however, the dividend payment increases the lower price bound of the European-style put. Because the put option is the right to sell the underlying asset at a fixed price, a discrete drop in the asset price such as one induced by the payment of a dividend on a stock serves to increase the value of the option. The arbitrage trades driving this relation are buy a put, buy a share of stock, and sell $I_t e^{-rt} + Xe^{-rT}$ risk-free bonds.

Lower Price Bound of American-Style Put

The lower price bound of the American-style put is

$$P \geq \max(0, Xe^{-rt} - S + I_t e^{-rt}, X - S) \quad (18)$$

The second term on the right-hand side is the present value of the exercise proceeds if the put is exercised just after the dividend payment. This lower price bound is supported by the arbitrage trades listed above for the European-style put. The third term on the right is the exercise proceeds if the put is exercised immediately. If $P < X - S$, a costless arbitrage profit can be earned by buying the put and the asset, and then exercising the put. The arbitrage profit is $X - S - P > 0$.

Early Exercise of American-Style Put Options

The early exercise behavior induced by the discrete cash dividend on the asset is different for the American-style put than it was for the call. If the third term exceeds the second in (18), the put will not be exercised early prior to the payment date. In that period the interest earned on the exercise proceeds of the option is less than the drop in the stock price from the payment of the dividend. For the third term to be larger than the second, that is,

$$Xe^{-rt} - S + I_t e^{-rt} > X - S$$

it must be the case that

$$I_t > X(e^{rt} - 1) \quad (19)$$

In other words, if the amount of the dividend amount exceeds the interest income that will accrue on the cash received if the put is exercised immediately, the put will not optimally be exercised early.

As in the case of the call, this argument can be generalized to handle the multiple dividends during the life of an American-style put. Again, consider a stock option. If the i th dividend is

greater than the interest that will accrue over the period,

$$I_t > X[e^{r(t-t_{i-1})} - 1] \tag{20}$$

the put will not be exercised before the dividend payment, as the illustration below shows.

We'll use an example to identify whether an American-style put option with an exercise price of 50 and one year remaining to expiration may be exercised early just after any of the dividend payments. Assume that the stock pays a quarterly dividend of 0.50 in 70 days, 161 days, 252 days, and 343 days. Assume the risk-free rate of interest is 5%.

Whether or not the put may be exercised early depends on the amount of the dividend payment in relation to the interest income that could be earned if the put were exercised immediately. For the first dividend, compute the values in expression (20), that is,

$$0.50 > 50[e^{0.05(70/365)} - 1] = 0.4818$$

This implies that the put will not be exercised before the first dividend payment in 70 days.

The computation for the second dividend is

$$0.50 > 50[e^{0.05(161/365 - 70/365)} - 1] = 0.6272$$

This implies that the put may be exercised in the period between the first and second dividends. The same is true between the second and third dividends, and the third and fourth dividends, as indicated below. Early exercise after

the fourth dividend is paid may also be optimal since no more dividends are paid during the option's life.

Quarter	Cash Dividend	Days to Dividend Payment	Years to Dividend Payment	Accrued Interest
1	0.50	70	0.1918	0.4818
2	0.50	161	0.4411	0.6272
3	0.50	252	0.6904	0.6272
4	0.50	343	0.9397	0.6272

Put-Call Parity for European-Style Options

Put-call parity for European-style options on assets with discrete noninterest cash flows is

$$c - p = S - I_t e^{-rt} - X e^{-rT} \tag{21}$$

To see this, assume the left-hand side of (21) is less than the right-hand side. If such is the case, an arbitrage profit can be made by selling the asset, selling the put, buying the call, and buying some risk-free bonds. The arbitrage is shown in Table 9. On day t , the net portfolio value is certain to be 0. The same is true on day T , when the cash dividend is made. Thus the value at time 0, $S - I_t e^{-rt} - X e^{-rT} + p - c$, represents the arbitrage profit and is positive if the left-hand side of (21) is less than the right-hand side. Since the market cannot be in equilibrium, arbitrage will continue until the net portfolio value goes to 0. When it does, the market is in equilibrium and (21) holds.

Table 9 Arbitrage Portfolio Trades Supporting European-Style Put-Call Parity Where the Underlying Asset Pays a Discrete Cash Dividend, $c - p = S - I_t e^{-rt} - X e^{-rT}$

Trades	Initial Investment	Cash Flow at t	Value on Day T	
			$S_T < X$	$S_T \geq X$
Sell asset	S	$-I_t$	$-\tilde{S}_T$	$-\tilde{S}_T$
Sell put option	p		$-(X - \tilde{S}_T)$	0
Buy call option	$-c$		0	$\tilde{S}_T - X$
Buy risk-free bonds	$-X e^{-rT} - I_t e^{-rt}$	I_t	X	X
Net portfolio value	$S - I_t e^{-rt} - X e^{-rT} + p - c$	0	0	0

Table 10 Arbitrage Trades Supporting American-Style Put-Call Parity Where the Underlying Asset Pays a Discrete Cash Dividend, $S - I_t e^{-rt} - X < C - P$

Trades	Initial Value	Ex-Day Value (t)	Put Exercised Early, Intermediate Value (τ)	Put Exercised Normally, Terminal Value (T)	
				$\tilde{S}_T \leq X$	$\tilde{S}_T < X$
Buy call	$-C$		\tilde{C}_τ	0	$\tilde{S}_T - X$
Sell put	P		$-(X - \tilde{S}_\tau)$	$-(X - \tilde{S}_T)$	0
Sell asset	S	$-I_t$	$-\tilde{S}_\tau$	$-\tilde{S}_T$	$-\tilde{S}_T$
Buy risk-free bonds	$-I_t e^{-rt} - X$	I_t	$Xe^{r\tau}$	Xe^{rT}	Xe^{rT}
Net portfolio value	$-C + P + S - I_t e^{-rt} - X$	0	$\tilde{C}_\tau + X(e^{r\tau} - 1)$	$X(e^{rT} - 1)$	$X(e^{rT} - 1)$

Put-Call Parity for American-Style Options

The put-call parity for American-style options on assets with discrete cash dividends is

$$S - I_t e^{-rt} - X \leq C - P \leq S - I_t e^{-rt} - X e^{-rT} \tag{22}$$

To understand why, we consider each inequality in (22) in turn. The inequality on the left can be derived by considering the values of a portfolio that consists of buying a call, selling a put, selling the stock, and buying $X + I_t e^{-rt}$ in risk-free bonds. Table 10 contains these trades as well as the net portfolio value.

In Table 10, we see that, if all positions stay open until expiration, the net portfolio value is positive independent of whether the terminal asset price is above or below the exercise price of the options. If the terminal asset price is above the exercise price, the call option is exercised, and the asset acquired at exercise price

X is used to deliver, in part, against the short asset position. If the terminal asset price is below the exercise price, the put is exercised. The asset received in the exercise of the put is used to cover the short stock position. In the event the put is exercised early at time τ , the investment in the risk-free bonds is more than sufficient to cover the payment of the exercise price, and the asset received upon delivery can be used to cover the short asset position. In addition, the call position remains open and has a nonnegative value. In other words, the combination of securities described in Table 10 will never have a negative future value. And, if the future value is certain to be nonnegative, the sum of the initial investment column must be nonpositive. In the absence of costless arbitrage opportunities, the left-hand inequality of (22) must hold.

The right inequality of (19) may be derived using the same portfolio used to prove European-style put-call parity. Table 11 contains the

Table 11 Arbitrage Trades Supporting American-Style Put-Call Parity Where the Underlying Asset Pays a Discrete Cash Dividend, $C - P < S - I_t e^{-rt} - X e^{-rT}$

Trades	Initial Value	Ex-Day Value (t)	Call Exercised Early, Intermediate Value (τ)	Call Exercised Normally, Terminal Value (T)	
				$\tilde{S}_T \leq X$	$\tilde{S}_T < X$
Sell call	C		$-(\tilde{S}_\tau - X)$	0	$-(\tilde{S}_T - X)$

Table 12 No-Arbitrage Price Relations For European- and American-Style Options on Assets Where the Underlying Asset Pays a Discrete Cash Dividend

Description	European-Style Options	American-Style Options
Lower price bound for call	$c \geq \max(0, S - I_t e^{-rt} - X e^{-rT})$	$c \geq \max[0, S - X e^{-rt}, S - I_t e^{-rt} - X]$
Lower price bound for put	$p \geq \max(0, X e^{-rT} - S + I_t e^{-rt})$	$P \geq \max(0, X - S, X e^{-rT} - S + I_t e^{-rt})$
Put-call parity relation	$c - p = S - I_t e^{-rt} - X e^{-rT}$	$S - I_t e^{-rt} - X \leq C - P$ $\leq S - I_t e^{-rt} - X e^{-rT}$

arbitrage portfolio trades. In this case, the net portfolio value at expiration is certain to be 0 should the option positions stay open until that time. In the event the American call option holder decides to exercise early, the portfolio holder delivers his share of stock, receives cash in the amount of the exercise price, and then uses the cash to retire his outstanding debt. After these actions are taken, the portfolio holder still has an open long put position and cash in the amount of $X[1 - e^{-r(T-\tau)}]$. Since the portfolio is certain to have nonnegative outcomes, the initial value must be negative or the right-hand inequality of (22) must hold.

Summary

This completes our derivations of arbitrage relations for European-style and American-style options on assets with discrete cash dividends. Options on dividend-paying stocks and on coupon-bearing bonds fall into this category. Before proceeding with a discussion of arbitrage relations for futures options, we summarize our results in Table 12.

NO-ARBITRAGE FUTURES OPTIONS RELATIONS

A *futures option* is like an asset option, except that if the option is exercised, a futures po-

sition is entered. Exercising a call option on a futures contract, for example, means that the holder will receive a long position in the futures at a price equal to the exercise price of the call.

Developing the lower bounds and put-call parity for European- and American-style futures options follows directly from the previous discussions. All we need to do is recall the prepaid version of the net cost of carry relations for futures: $Fe^{-rT} = Se^{-iT}$ where noninterest costs are modeled as a continuous rate, and $Fe^{-rT} = S - Ie^{-rt}$ where noninterest costs are modeled as a discrete flow. Substituting $Fe^{-rT} = Se^{-iT}$ into the no-arbitrage price relations summarized in Table 7 or $Fe^{-rT} = S - Ie^{-it}$ in the relations summarized in Table 12 produces the no-arbitrage price relations for futures options summarized in Table 13. The arbitrage portfolios supporting each of these relations are the same as those used to derive the relations for the asset throughout the entry.

NO-ARBITRAGE INTERMARKET RELATIONS

In many cases, both asset options and futures options trade concurrently. The Chicago Board Options Exchange, for example, lists options on the S&P 500 index, while the Chicago Mercantile Exchanges lists options on the S&P 500

Table 13 No-Arbitrage Price Relations For European- and American-Style Options on Futures Contracts

Description	European-Style Options	American-Style Options
Lower price bound for call	$c \geq \max[0, e^{-rT}(F - X)]$	$C \geq \max(0, F - X)$
Lower price bound for put	$p \geq \max[0, e^{-rT}(X - F)]$	$P \geq \max(0, X - F)$
Put-call parity relation	$c - p = e^{-rT}(F - X)$	$F e^{-rT} - X < C - P < F - X e^{-rT}$

futures (which, in turn, is written on the S&P 500 index). The prices of asset options are inextricably linked to the prices of futures options. Under the assumption that the futures and options expire simultaneously and that the exercise prices of the asset and futures options are the same, a number of no-arbitrage price relations may be derived. Next we present such relations for European-style and American-style options.

European-Style Options

The price of a European-style asset option is equal to the price of the corresponding futures option, that is,

$$c(S) = c(F) \quad (23a)$$

and

$$p(S) = p(F) \quad (23b)$$

The reason is that at expiration the payoffs of the asset option and the futures option are identical. Suppose, for the sake of illustration, that the price of a call on a futures exceeds the price of a call on an asset. In such a situation, costless arbitrage profits may be earned by buying the asset call and selling the futures call, as is shown in Table 14. The long asset option position pays nothing at expiration if the terminal asset price is less than the exercise price and pays $\tilde{S}_T - X$ if the terminal asset price exceeds the exercise price. At the same time, the short futures option position expires worthless at expiration if the terminal futures (asset) price is less than the exercise price and costs $-(\tilde{F}_T - X)$ if the terminal futures (asset) price exceeds the exercise price. But, since $\tilde{F}_T = \tilde{S}_T$, the net port-

folio value is certain to be zero. A portfolio that is certain to pay nothing on day T must cost nothing. Hence, in the absence of costless arbitrage opportunities, European-style asset options and European-style futures options have the same price.

American-Style Options

The relation between the price of an American-style asset option and the price of the corresponding futures option depends on whether the futures price is greater than the asset price or not. If $F > S$,

$$C(S) < C(F) \quad (24a)$$

and

$$P(S) > P(F) \quad (24b)$$

To see this, consider the American-style call options. Since both the call on the futures and the call on the asset may be exercised early, we can compare the early exercise proceeds to establish which has greater value. The call on the asset has immediate early exercise proceeds of $S - X$ and the call on the futures has early exercise proceeds of $F - X > S - X$. Thus as long as there is some chance of early exercise, the call on the futures is worth more than the call on the asset and the put on the asset is worth more than the put on the futures.

For cases where futures price is less than the asset price, the opposite results hold, that is,

$$C(S) > C(F) \quad (25a)$$

and

$$P(S) < P(F) \quad (25b)$$

Table 14 Arbitrage Portfolio Trades Demonstrating the Equivalence of Prices of European-Style Call Options on an Asset and a Futures, $c(F) = c(S)$

Trades	Initial Investment	Value on Day T	
		$S_T < X$	$S_T \geq X$
Buy call option on asset	$-c(S)$	0	$\tilde{S}_T - X$
Sell call option on futures	$c(F)$	0	$-(\tilde{F}_T - X) = -(\tilde{S}_T - X)$
Net portfolio value	$c(F) - c(S)$	0	0

Table 15 No-Arbitrage Relations Between the Prices of Asset Options and Futures Options

Description	European-Style Options	American-Style Options
Call	$c(S) = c(F)$	$C(S) < C(F)$ if $F > S$ $C(S) > C(F)$ if $F < S$
Put	$p(S) = p(F)$	$P(S) > P(F)$ if $F > S$ $P(S) < P(F)$ if $F < S$

The previous arbitrage argument is merely reversed. Table 15 summarizes the results.

KEY POINTS

- Under the assumption that no costless arbitrage (i.e., free money) opportunities are available in the marketplace, no-arbitrage price relations for European- and American-style options can be developed.
- The net cost of carry of the underlying asset plays an important role. Consequently, it is necessary to model interest cost as a constant continuous rate and the noninterest cost as a continuous rate or as a discrete flow, depending on the nature of the underlying asset.

For options on stock indexes, currencies, and some commodities, the continuous rate assumption is most appropriate. For options on stocks, bonds, and other commodities, the discrete flow assumption is preferred.

- With the assumptions regarding net cost of carry, lower price bounds, put-call parity price relations, and intermarket price relations can be derived for both European-style and American-style options on an asset and on a forward/futures.
- For American-style options, there is always the prospect of early exercise. Under certain circumstances regarding the cost of carry, the holder of an American-style call option would never (rationally) exercise early. In the case of an American-style put, there is always some prospect of early exercise, so the American-style put is always worth more than the European-style put.

- Perhaps most important is the no-arbitrage price relation between the price of a put and the price of a call. This relation, called the put-call parity relation, arises from simultaneous trades in the call, the put, and the asset.
- With respect to intermarket price relations, the prices of asset options are inextricably linked to the prices of futures options. Under the assumption that the futures and options expire simultaneously and that the exercise prices of the asset and futures options are the same, a number of no-arbitrage price relations may be derived.

NOTES

1. *European-style* options can be exercised only on expiration day, while *American-style* options can be exercised at any time up to and including the expiration day. Both types of options are traded on exchanges and in OTC markets.
2. Under the continuous cost of carry rate assumption, the continuously paid income received from holding the asset is immediately reinvested in more units of the asset, so that e^{-iT} units on day 0 grows to one unit on day T . For a short asset position, the reverse applies in the sense that our liability (in terms of number of units owed) grows at rate i .
3. It is also worthwhile to note that the lower price bound of the call can be re-expressed relative to the forward/futures prices. The net cost of carry relation for forwards/futures prices is $fe^{-rT} = Se^{-iT}$. Substituting the cost of carry relation into (4), $c \geq \max(0, fe^{-rt} - Xe^{-rT})$.
4. The distinction between value and price is subtle, but important. A price is what we observe for the security in the marketplace; a value is what we believe a security is worth. If the value exceeds the price, the security is underpriced, and, if the value is less than the price, the security is overpriced.
5. Note that we are not making any judgment on whether the call price is too high or too

low *per se*. We are saying only that the call is incorrectly priced (in this case it is priced too low) *relative* to the price of the underlying asset. To execute the arbitrage, we must trade both the call and the underlying asset, so that we make money when their prices come back into line relative to each other. In this example, the prices come back into line with each other for certain at the option's expiration.

6. To exit a long position in an American-style call option, we have three alternatives. First, we can hold it to expiration, at which time we will (a) let it expire worthless if it is out of the money or (b) exercise it if it is in the money. Second, we can exercise it immediately, receiving the difference between the current asset price and the exercise price. Third, we can sell it in the marketplace. There is, after all, an active secondary market for standard calls and puts.
7. This point was first demonstrated by Merton (1973) for call options on nondividend-paying stocks. He refers to such options as being worth more "alive" than "dead."
8. In the expression on the right-hand side of (10), the third term is greater than the second term over some range for S , independent of the level of i .
9. The term, "put-call parity," was first coined by Stoll (1969) in the first academic study to develop and test the relation.
10. If we buy a put option, we pay the premium today for the right to sell the underlying asset at the exercise price. If we sell the put, we collect the premium today but have the obligation to deliver the asset and receive the exercise price if the put option buyer chooses to exercise.
11. By not exercising in the period prior to ex-dividend, the call option holder enjoys the benefits of implicitly earning interest on the dividend and the exercise price of the call. By not exercising after the ex-dividend date but before expiration, the call option holder enjoys the benefit of implicitly earning interest on the exercise price of the call.

Introduction to Contingent Claims Analysis

EDWIN H. NEAVE, PhD

Professor Emeritus, School of Business, Queen's University, Kingston, Ontario

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Contingent claims are a tool for valuing securities and for analyzing the effects of risky financial decisions. Contingent claims analysis can be used to value any kind of financial instrument, including such apparently exotic instruments as put and call options and convertible securities. Contingent claim analysis defines risky outcomes relative to states of the world, and uses claims to represent and value state outcomes. Thus given a definition of risky states, all financial instruments and arrangements can be represented as combinations of contingent claims on those states. Theoretically complete markets assume claims can be traded on every state of the world, but in practice markets are not likely to be complete at any point in time. Since in practice market incompleteness will inhibit certain risk management strategies, in so doing it also provides incentives to create new instruments that can be used to manage and to value claims on additional states of the world.

Contingent claims analysis is used in financial modeling to value any financial instrument, including such apparently exotic instruments as put and call options and convertible securities. In this entry, we discuss this important tool. We begin by explaining the notion of states of the world, a way of classifying risky outcomes whose value can then be represented using contingent claims. After providing examples of valuation using contingent claims, we introduce the concept of incomplete markets and consider its importance for modeling real-world financial arrangements. We then examine some financial instruments and arrangements that can be used to trade or to manage risks.

STATES OF THE WORLD

The idea of *states of the world* is useful for thinking about convenient ways to model risky payoffs. In a two-time-point model, states of the world are defined as those future events that matter to the decision problem being considered. These states of the world are defined by the decision maker to be mutually exclusive and collectively exhaustive. Using an example given by Savage (1951), if one is about to break a ninth egg into a bowl already containing eight other eggs, the relevant states of the world could be whether the ninth egg is rotten and would hence spoil the others. (Here we presume the

rotteness of an egg is not discernible until the egg has been broken and fallen into the bowl.)

In a second example more closely related to finance, an investor might be concerned with the future price of a share of stock, and this price might in turn depend on economic conditions. Suppose the investor defines (1) “states” to represent economic conditions, and (2) “future prices” to be the following list of possible share prices that may obtain at the time a given state is actually realized:

State	Future Price
1	\$10
2	\$8
3	\$6

For example, state 1 might mean that the industry in which the firm operates faces buoyant market conditions; state 2, conditions that are neither good nor bad; and state 3, conditions that are depressed. In each state, the effect is registered on the stock price.

We shall usually associate probabilities with the states; for example, p_i might represent the probability that state i will actually occur; that is, $i = 1, 2, 3$. Because the states are mutually exclusive, only one can actually occur; because they are collectively exhaustive, one of the three must occur. Hence $\sum_i p_i = 1$.

Note that although in this chapter we make less use of multiperiod models using contingent claims, we can also define states at different points in time, for example, the states of the world at different times.

CONTINGENT CLAIMS AND THEIR VALUE

A *unit contingent claim* is a security that will pay an amount of \$1 if a certain state of the world is actually realized, but nothing otherwise. A claim that pays \$1 if state i is realized is frequently called a *unit claim* on state i . A unit contingent claim is also referred to as a *primary security* or *Arrow-Debreu security* (so named after

the economists who introduced them—Arrow [1964] and Debreu [1959]).

Accordingly, the future stock price described earlier may be regarded as equivalent to a package containing all of the following:

Ten unit claims on state 1
Eight unit claims on state 2
Six unit claims on state 3

The idea of a contingent claim is thus useful for expressing, in terms of fundamental units, exactly what a given security’s payoff may be in different possible states of the world.

It may take a little imagination to come up with real-world examples of claims, and those real-world examples are not numerous. (A ticket to win on a horse race is an example of a claim; a fire insurance policy is another. One example of a unit claim is an option that pays off \$1 if the value of some underlying asset exceeds a fixed dollar value.) But packages of unit claims represent perfect substitutes for the more ordinary types of securities such as stocks or bonds, and we shall frequently find it useful to employ claims to help understand price relations between securities. For example, if we assume a perfectly competitive financial market along with a description of future events in terms of states of the world, certain price relationships between securities and contingent claims must obtain. This means in turn that certain predictable relationships between securities prices must also obtain.

To see these relationships, suppose that we can describe the world using two states and that two stocks are available, stock A and stock B. We assume the stocks’ future prices have the following distributions:

	Stock A	Stock B
1	\$10	\$7
2	\$8	\$9

Let $A(0)$ = denote the time 0 price of stock A and $B(0)$ = the time 0 price of stock B, and suppose these prices admit no arbitrage opportunities. Now if we let C_1 and C_2 represent the

time 0 prices of unit claims on states 1 and 2, we can use the foregoing information about stock prices and payoffs to find the time 0 prices C_1 and C_2 . Purchasing stock A for \$6 is equivalent to buying a package of 10 unit claims on state 1 and 8 unit claims on state 2, while buying stock B for \$5 is equivalent to buying a package of 7 unit claims on state 1 and 9 unit claims on state 2. Since the unit claims comprising the two stocks are perfect substitutes, they must sell for the same prices in a perfect market. Hence we can write

$$10C_1 + 8C_2 = \$6$$

$$7C_1 + 9C_2 = \$5$$

which can be solved to obtain

$$C_1 = \$\frac{7}{17}, \quad C_2 = \$\frac{4}{17}$$

We can use the same reasoning to find the risk-free rate of return that must obtain in this market. Since a risk-free instrument is one that offers the same payoff irrespective of which state of the world obtains, we wish to find a combination of the two stocks that gives the same time 1 payoff, here denoted k , in either state of the world. That is, the following equation must be solved for α :

$$\alpha \begin{pmatrix} 10 \\ 8 \end{pmatrix} + (1 - \alpha) \begin{pmatrix} 7 \\ 9 \end{pmatrix} = \begin{pmatrix} k \\ k \end{pmatrix}$$

We can write the payoff k as equal to either of the following payoffs:

$$10\alpha + 7(1 - \alpha) = 8\alpha + 9(1 - \alpha)$$

which implies that

$$2\alpha = 2(1 - \alpha)$$

so that $\alpha = \frac{1}{2}$. The riskless payoff is then $\frac{1}{2}(10) + \frac{1}{2}(7) = \8.50 , and this can be obtained for a price equal to $\frac{1}{2}(6) + \frac{1}{2}(5) = \5.50 , since a portfolio composed of equal proportions of the two stocks creates the riskless investment. Accordingly, the risk-free rate of return is

$$\frac{\$8.50 - \$5.50}{\$5.50} = \frac{6}{11} = 54.55\%$$

Of course, this is not necessarily a realistic number for a risk-free rate of interest. (Whether it is realistic or not depends on the length of the time period under consideration, a matter we have left unspecified.) However, our purpose here is to develop illustrative calculations to display relations between contingent claims, and for this purpose particular sizes of numbers are not really important.

Another way of making a riskless investment is to buy one of each available unit claim, that is, one claim on state 1 and one claim on state 2. Such a portfolio gives a certain payoff of \$1 for an investment cost of

$$\$ \frac{4}{17} + \$ \frac{7}{17} = \$ \frac{11}{17}$$

The rate of return on this investment is then

$$\frac{\$1 - \$ \frac{11}{17}}{\$ \frac{11}{17}} = \frac{17 - 11}{11} = \frac{6}{11} = 54.55\%$$

just as before.

INVESTOR'S UTILITY MAXIMIZATION IN CONTINGENT CLAIMS MARKETS

In this section, we describe how an investor may solve the utility maximization problem when facing risk in a market for contingent claims. For our illustration, we shall continue with stocks A and B from the previous section. Further, we shall assume the investor's initial wealth to be \$600. This scenario is summarized in Table 1. We let w_1 represent wealth if state 1 occurs and correspondingly for w_2 , and we may plot these data in (w_1, w_2) space, as shown in Figure 1. Note that the previously determined riskless position of dividing the purchases to obtain an equal number of each security (54.5 of each) is also shown and generates a riskless terminal wealth position of $w_1 = w_2 = \$926.50$.

Table 1 Summary of Terminal Wealth in Two States

	No. of Shares Purchased	Terminal Wealth	
		State 1	State 2
Purchases A only	100	\$1,000	\$ 800
Purchases B only	120	\$ 840	\$1,080

We can also use another way to calculate the value of the claims' combinations at time 1. We can write the equation of the straight line in Figure 1 as

$$w_2 = a - bw_1$$

so that for the time 1 price of stock A we have

$$\$800 = a - \$1,000b$$

while for the time 1 price of stock B we have

$$\$1,080 = a = \$840b$$

Solving these two simultaneous equations, we find $b = 0.175$ and $a = \$2,550$. Thus, when $w_1 = 0$, $w_2 = \$2,550$, while when $w_2 = 0$, $w_1 = \$1,457$, which are the two intercepts of the line on their respective axes in Figure 1.

Now if $w_2 = 0$, we have the case of a claim (primary security) on state 1. (The security pays \$1,457 in state 1 and nothing otherwise.) The price of this claim can be calculated by dividing initial wealth by the maximum wealth obtained if state 1 occurs, or $\$600/\$1,457 = 0.41$ ($= \frac{7}{17}$). Similarly, the price of primary security 2 is $\$600/\$2,550 = 0.24$ ($= \frac{4}{17}$), and our earlier results are confirmed.

Note that in Figure 1 the investor's time 1 position is some point on the line from A to B. How could the investor obtain a terminal wealth position lying beyond these points? The investor could engage in short sales, that is, selling shares not currently owned, for delivery when the unknown future state of the world is revealed. In this transaction the investor obtains cash from the time 0 sale of one security and uses it to buy the other. In so doing, the investor promises later to buy the security sold short at whatever price will be prevailing and deliver it. Note that there is a potential for large gains or losses in such transactions. Here the initial wealth will be used as a constraint and we shall require that at worst the investor will

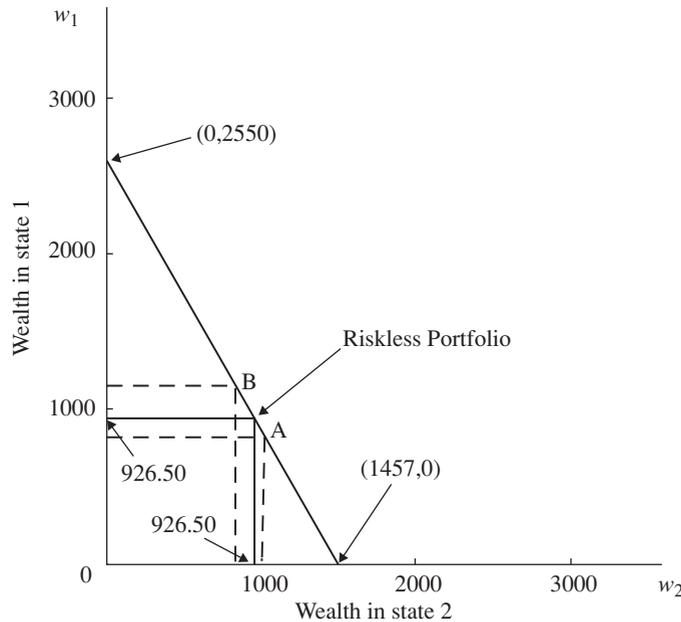

Figure 1 Market Opportunity Line, Showing Implied Prices of Unit Claims. Note: w_1 represents wealth if state 1 occurs and correspondingly for w_2 .

have zero terminal wealth if he or she guesses incorrectly. That is, no net borrowing is permitted at the end of the period so that the investor cannot go beyond the intercepts in Figure 1.

To illustrate, consider point $w_1 = \$1,457$, $w_2 = 0$. Let n_A be the number of shares of stock A and n_B the number of shares of stock B purchased. If state 1 occurs, the terminal wealth will be

$$10n_A + 7n_B = \$1,457$$

while if state 2 occurs, we must have

$$8n_A + 9n_B = 0$$

Solving these equations simultaneously, we find $n_B = 343$. If the investor sells short 343 shares of stock B at the current price of \$5, he or she will receive \$1,715. Combining this with the initial wealth of \$600 gives \$2,315, so this investor may buy $\$2,315/\$6 = 386 n_A$ at \$6 per share. If state 1 eventuates, the investor will receive \$3,860 (\$10 for the 386 shares) but now must pay \$2,401 (\$7 for 343 shares) for stock B shares to cover the short position. The net terminal wealth is $\$3,860 - \$2,401 = \$1,459$ (difference due to rounding), as required. In state 2, the terminal wealth will be equal to \$3,088 (386 shares times \$8 per share) reduced by the cost to repurchase stock B to cover the short position, 343 shares at \$9 per share or \$3,087. Therefore, the net terminal wealth is equal to zero (the calculations show it is \$1 but that is due to rounding).

Note that none of the points we have considered will necessarily be a utility-maximizing point. To determine this point, it is necessary to know the investor's utility function in (w_1, w_2) space. The optimal portfolio for the investor satisfies the tangency condition that the slope of the wealth constraint (the ratio of the prices of the unit claims) equals the slope of the indifference curve (marginal rate of substitution of state 1 consumption for state 2 consumption).

The point of the foregoing demonstration is to show first that every security can be viewed as a bundle of unit claims and thus represents a combination of positions regarding future

states of the world. Moreover, in these circumstances an investor can attain any point along the market opportunity line. If, on the other hand, there are fewer securities than the number of distinct states, the individual's optimal consumption choices may not be attainable. The significance of this will be explored in the next section.

Although we do not discuss it here, the real power of the contingent claim analysis is in providing the basis for valuing complex financial instruments and financial arrangements.

INCOMPLETE MARKETS FOR CONTINGENT CLAIMS

A market is said to be a *complete market* when economic agents can structure any set of future state payoffs by investing in a portfolio of unit contingent claims (i.e., primary securities). A financial market is said to be *incomplete* if the number of (linearly) independent securities traded in it is smaller than the number of distinct states of the world. Clearly, market incompleteness depends on how states of the world are defined. However, since the number of states of the world needed to describe a typical financial market is likely to be large, the possibility that real-world financial markets will be incomplete is a very real one.

The importance of market incompleteness is best introduced by an example. Let us consider an economy with three possible states of the world and suppose only two securities (taking the form of unit claims for ease of exposition) are traded in it. We describe the securities in terms of their time 1 market value, for each state of the world, as in Table 2. It is apparent from the table that weighted averages of the two unit claims can be used to create packages with time 1 distributions of values ranging between zero and unity, the actual outcome depending on whether state 1 or state 2 obtains. However, an investor cannot create an income claim of other than zero in state 3 by using just the existing two unit claims. Moreover, no

Table 2 Market Values of Two Securities at Time 1

Security	States of the World		
	1	2	3
1	1	0	0
2	0	1	0

investor can arrange a risk-free investment in this example, because it is not possible to guarantee the same return in every state of the world by using just the available securities.

The situation is quite different if a third unit claim worth \$1 in state 3 and zero in the other states becomes available. Now the number of claims equals the number of distinct states, and a risk-free investment can now be arranged.

We are now ready to discuss some practical implications of market incompleteness. It is obvious from the foregoing example that investor choice is restricted in incomplete markets. Moreover if investor choices are restricted, the investors will never be better off, and are likely to be worse off, than would be the case if markets were complete (i.e., if the restrictions were removed). In such situations, it is to be expected that if ways of completing the market can be found, those possibilities are likely to be utilized. That is, in the context of incomplete financial markets the appearance of new instruments might be regarded as attempts to provide investors with financial opportunities not otherwise available. The appearance of *derivatives* (options, futures, and swaps) might be examples of such attempts. Mossin (1977) argues that the preference existing firms show for organizing new activities as separate corporations may be another indication of attempts to deal with market incompleteness.

FINANCIAL INSTRUMENTS AS CONTINGENT CLAIMS

Most financial instruments can be bought or sold, but not all of them are actively traded in

financial markets. For example, a common form of contingent claim (and one that is close in concept to a unit claim) is a lottery ticket. In its simplest form this claim results in its holder winning either a positive prize or zero. Accordingly, this lottery ticket represents a claim that can be valued using two states of the world. Obviously, if a lottery has several different prizes, several states of the world may need to be defined in order to describe it completely. But lottery tickets, once issued, are rarely traded again. The same is true of such other contingent claims as the tickets obtained when betting on horse races or similar contests.

An insurance policy is a contingent claim that comes closer to our usual notions of a financial instrument, but again it is rarely traded in the financial markets. On the other hand, put or call options, representing contingent claims for selling or buying securities or financial indexes at prespecified prices, trade actively on such organized exchanges. Rights and warrants are other examples of contingent claims in that they permit, but do not require, the holder to buy securities on prespecified terms.

There are also securities that have *embedded derivatives* in them, derivatives that are not traded separately from the instrument itself. For example, a *callable bond* is a bond that grants the issuer the right to redeem the bond at some time in the future and at a specified price. That is, a callable bond can be viewed as a straight bond with an embedded call option granted to the issuer. A *puttable bond* is a bond that grants the investor the right to sell (i.e., put) the bond to the issuer in the future at a specified price. Hence, the bond structure can be viewed as a straight bond with an embedded put option. *Convertible securities*, which include convertible bonds or convertible preferred stocks, represent contingent claims in that they typically allow the owner to exchange the original issue for other securities, usually common stock, and they are callable. Some convertible securities even include an embedded put option.

KEY POINTS

- Contingent claims analysis and contingent strategies are tools for dealing with risk in financial decision making.
- Contingent claims analysis uses the notion of states of the world in assessing future risky payoffs.
- A unit contingent claim (also known as a primary security or Arrow-Debreu security) is a security that has a payoff of \$1 if a certain state of the world is actually realized, but nothing in all other states.
- A contingent claim that pays off \$1 if state i is realized is also referred to as a unit claim on state i .
- Although few unit contingent claims exist in reality, claims represent a useful tool to employ in valuing securities and in understanding relations among them.
- An investor may solve the utility maximization problem when facing risk in a market for contingent claims.
- Using contingent claims analysis, an investor can obtain a terminal wealth position beyond what can be obtained by simply buying securities with initial wealth by engaging in short sales (i.e., selling shares not currently owned, for delivery when the unknown future state of the world is revealed). The outcomes in this case are more risky than they would be in the absence of short selling.
- Every security can be viewed as representing a bundle of unit claims and thereby further represents a combination of positions (long and short) regarding future states of the world.
- If the number of (linearly) independent securities traded is smaller than the number of distinct states of the world, the financial market is said to be incomplete.
- Because the number of states of the world necessary to describe a well-functioning financial market is likely to be large, the possibility that real-world financial markets will be incomplete is a very real one.
- Although most financial instruments representing contingent claims can be bought or sold, there are financial instruments or financial arrangements that are not actively traded in financial markets.

Black-Scholes Option Pricing Model

SVETLOZAR T. RACHEV, PhD, DrSci

Frey Family Foundation Chair Professor, Department of Applied Mathematics and Statistics, Stony Brook University; and Chief Scientist, FinAnalytica

CHRISTIAN MENN, Dr Rer Pol

Managing Partner, RIVACON

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: The most popular continuous-time model for option valuation is based on the Black-Scholes theory. Although certain drawbacks and pitfalls of the Black-Scholes option pricing model have been understood shortly after its publication in the early 1970s, it is still by far the most popular model for option valuation. The Black-Scholes model is based on the assumption that the underlying follows a stochastic process called geometric Brownian motion. Besides pricing, every option pricing model can be used to calculate sensitivity measures describing the influence of a change in the underlying risk factors on the option price. These risk measures are called the “Greeks” and their use will be explained and described.

In this entry, we look at the most popular model for pricing options, the Black-Scholes model, and look at the assumptions and their importance. We also explain the various Greeks that provide information about the sensitivity of the option price to changes in the factors that the model tells us affects the value of an option.

MOTIVATION

Let us assume that the price of a certain stock in June of Year 0 ($t = 0$) is given to be $S_0 = \$100$. We want to value an option with strike price

$X = \$110$ maturing in June of Year 1 ($t = T$). As additional information we are given the continuously compounded one-year risk-free interest rate $r = 5\%$. Figure 1 visualizes potential paths of the stock between $t = 0$ and $t = T$. How can we define a reasonable model for the stock price evolution?

It is clear that the daily changes or the change between the current and the next quotes cannot be predicted and can consequently be seen as realizations of random variables. However, we know that if we are investing in stocks then we can expect a rate of return in the long run which is higher than the risk-free rate. Let us denote

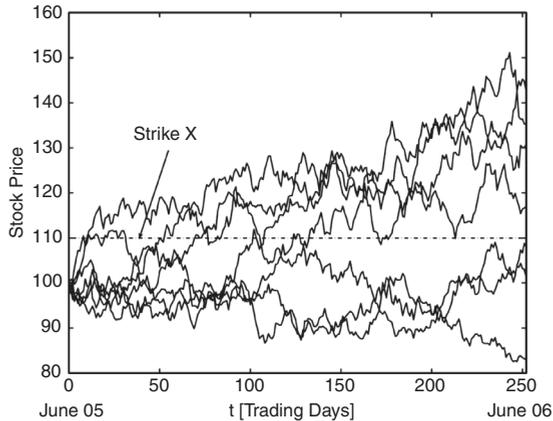

Figure 1 Possible Paths of the Stock Price Evolution over One Year with $S_0 = \$100$ and $X = \$110$

that unknown expected rate of return as μ . Here and in the rest of this entry, we assume that the stock pays no dividend.

Furthermore, we know that stock returns exhibit random fluctuations called volatility. Let σ denote the unknown yearly rate of volatility. Here and below we have implicitly assumed that the expected return and the volatility of the stock are time independent. This assumption might be violated in practice. Formalizing our ideas about the stock price we come up with the following equation for the return of the stock in a small time interval of length Δt :

$$\underbrace{\frac{S_{t+\Delta t} - S_t}{S_t}}_{\text{Return in period } [t, t+\Delta t]} = \mu \cdot \Delta t + \underbrace{\sigma \cdot \varepsilon_t^{\Delta t}}_{\text{“Stochastic noise”}}$$

The stochastic noise $\sigma \cdot \varepsilon_t^{\Delta t}$ should have the following properties:

- No systematic influence: $E(\varepsilon_t^{\Delta t}) = 0$.
- No dependence between the noise of different dates: The random variables ε_t and ε_s are independent for $s \neq t$.
- The variance of the noise is proportional to the length of the time interval Δt .

One possible model for the noise process is provided by a stochastic process called Brownian motion. A detailed discussion of Brownian motion is beyond the scope of this entry, but

we provide a brief discussion of its defining properties.

Brownian motion is a stochastic process $(W_t)_{t \geq 0}$ in continuous time that has the following four properties:

1. $W_0 = 0$, that is, Brownian motion starts at zero.
2. $(W_t)_{t \geq 0}$ is a process with homogeneous and independent increments.
3. Any increment $W_{t+h} - W_t$ is normally distributed with mean zero and variance h .
4. The paths of $(W_t)_{t \geq 0}$ are continuous.

The increments of Brownian motion are an appropriate candidate for the stochastic noise in our stock price model and we define:

$$\varepsilon_t^{\Delta t} = W_{t+\Delta t} - W_t$$

From its defining properties, we know that the increments of the Brownian motion are independent and that the variance of the increments is proportional to the length of the considered time interval. Additionally, the expectation of the increments is zero.

With this definition, it is possible to write the equation for the return process in the following form:

$$\frac{S_{t+\Delta t} - S_t}{S_t} = \mu \Delta t + \sigma (W_{t+\Delta t} - W_t)$$

If we decrease the length Δt of the time interval over which the increment is considered constant, then we can switch to a “differential type” notation:

$$\frac{dS_t}{S_t} = \mu \cdot dt + \sigma \cdot dW_t, \quad t \geq 0$$

The process defined in the above equation is called *geometric Brownian motion*. In explicit notation the geometric Brownian motion possesses the following form

$$S_t = S_0 e^{\left(\mu - \frac{1}{2}\sigma^2\right)t + \sigma W_t}$$

and S_t is lognormally distributed. This process is used in the Black-Scholes model to describe the stock price dynamic. Additionally,

the model assumes the existence of a risk-free asset—called money market account or bond—with the following dynamic:

$$\frac{dB_t}{B_t} = r \cdot dt, \quad t \geq 0 \Leftrightarrow B_t = B_0 e^{rt} \cdot t \geq 0 \quad (1)$$

BLACK-SCHOLES FORMULA

Black and Scholes (1973) have shown that it is possible—under some assumptions discussed in this section—to duplicate the payoff of a European call option with a continuously rebalanced portfolio consisting of the two assets S and B . This means that the price of the call option equals the initial costs for starting the hedging strategy.

The *Black-Scholes option pricing model* computes the fair (or theoretical) price of a European call option on a nondividend-paying stock with the following formula:

$$C = S\Phi(d_1) - Xe^{-rT}\Phi(d_2) \quad (2)$$

where

$$d_1 = \frac{\ln(S/X) + (r + 0.5\sigma^2T)}{\sigma\sqrt{T}} \quad (3)$$

$$d_2 = d_1 - \sigma\sqrt{T} \quad (4)$$

where

- $\ln(\cdot)$ = natural logarithm
- C = call option price
- S = current stock price
- X = strike price
- r = short-term risk-free interest rate in percent per annum
- $e = 2.718$ (natural antilog of 1)
- T = time remaining to the expiration date (measured as a fraction of a year)
- σ = expected return volatility for the stock (standard deviation of the stock's return in percent per annum)
- $\Phi(\cdot)$ = the cumulative distribution function of a standard normal distribution

The option price derived from the Black-Scholes option pricing model is “fair” in the sense that if any other price existed in a market

where all the assumptions of the Black-Scholes model are fulfilled, it would be possible to earn riskless arbitrage profits by taking an offsetting position in the underlying stock. That is, if the price of the call option in the market is higher than that derived from the Black-Scholes option pricing model, an investor could sell the call option and buy a certain number of shares in the underlying stock. If the reverse is true, that is, the market price of the call option is less than the “fair” price derived from the model, the investor could buy the call option and sell short a certain number of shares in the underlying stock. This process of hedging by taking a position in the underlying stock allows the investor to lock in the riskless arbitrage profit. The number of shares necessary to hedge the position changes as the factors that affect the option price change, so the hedged position must be changed constantly.

COMPUTING A CALL OPTION PRICE

To illustrate the Black-Scholes option pricing formula, assume the following values:

- Strike price = \$45
- Time remaining to expiration = 183 days
- Current stock price = \$47
- Expected return volatility = Standard deviation = 25% per annum
- Risk-free rate = 10% per annum

In terms of the values in the formula:

- $S = 47$
- $X = 45$
- $T = 0.5$ (183 days/365, rounded)
- $\sigma = 0.25$
- $r = 0.10$

Substituting these values into equations (3) and (4):

$$d_1 = \frac{\ln(47/45) + (0.10 + 0.5[0.25]^2)0.5}{0.25\sqrt{0.5}} = 0.6172$$

$$d_2 = 0.6172 - 0.25\sqrt{0.5} = 0.440443$$

From a normal distribution table,

$$\Phi(0.6172) = 0.7315 \quad \text{and} \quad \Phi(0.4404) = 0.6702$$

Then

$$C = \$47(0.7315) - \$45(e^{-(0.10)(0.5)})(0.6702) = \$5.69$$

Table 1 shows the option value as calculated from the Black-Scholes option pricing model for different assumptions concerning (1) the standard deviation for the stock's return (that is, expected return volatility); (2) the risk-free rate; and (3) the time remaining to expiration. Notice that the option price varies directly with three

Table 1 Comparison of Black-Scholes Call Option Price Varying One Factor at a Time

Base Case	
Call option:	
Strike price = \$45	
Time remaining to expiration = 183 days	
Current stock price = \$47	
Expected return volatility = Standard deviation of a stock's return = 25%	
Risk-free rate = 10%	
Holding All Factors Constant except Expected Return Volatility	
Expected Price Volatility	Call Option Price [\$]
15% per annum	4.69
20	5.17
25 (base case)	5.59
30	6.26
35	6.84
40	7.42
Holding All Factors Constant Except the Risk-Free Rate	
Risk-Free Interest Rate, % per annum	Call Option Price [\$]
7%	5.27
8	5.41
9	5.50
10 (base case)	5.69
11	5.84
12	5.99
13	6.13
Holding All Factors Constant except Time Remaining to Expiration	
Time Remaining to Expiration	Call Option Price [\$]

60	3.52
91	4.15
183 (base case)	5.69
273	6.99

variables: expected return volatility, the risk-free rate, and time remaining to expiration. That is: (1) the lower (higher) the expected volatility, the lower (higher) the option price; (2) the lower (higher) the risk-free rate, the lower (higher) the option price; and (3) the shorter (longer) the time remaining to expiration, the lower (higher) the option price.

SENSITIVITY OF OPTION PRICE TO A CHANGE IN FACTORS: THE GREEKS

In employing options in investment strategies, an asset manager or trader would like to know how sensitive the price of an option is to a change in any one of the factors that affect its price. Sensitivity measures for assessing the impact of a change in factors on the price of an option are referred to as the *Greeks*. In this section, we will explain these measures for the factors in the Black-Scholes model. Specifically, we discuss measures of the sensitivity of a call option's price to changes in the price of the underlying stock, the time to expiration, expected volatility, and interest rate. These factors can be divided into "market factors" and "model factors." The underlying price and the time to expiration are market factors, whereas the volatility and the interest rate are model factors. The special aspect about the latter variables is that they are assumed to be constant within the model. By admitting that these parameters can change as well, we are admitting that the model is inconsistent with reality. Table 2 gives an overview and lists the sensitivities of the option price with respect to all parameters of the Black-Scholes model.

Price of a Call Option Price and Price of the Underlying: Delta and Gamma

In developing an option-pricing model, we have seen the importance of understanding the relationship between the option price and the

Table 2 Sensitivities of the Option Price with Respect to Each Parameter of the Black-Scholes Model

Parameter	Corresponding Greek	Analytic Expression
Stock price S	Delta	$\Delta = \frac{\partial C}{\partial S} = \Phi(d_1)$
Stock price S (convexity adjustment)	Gamma	$\Gamma = \frac{\partial^2 C}{\partial S^2} = \frac{\varphi(d_1)}{S\sigma\sqrt{T}}$
Volatility σ	Vega	$v = \frac{\partial C}{\partial \sigma} = S \cdot \varphi(d_1) \cdot T$
Time	Theta	$\Theta = -\frac{\partial C}{\partial T} = -\frac{S\varphi(d_1)\sigma}{2\sqrt{T}} - rXe^{-rT}\Phi(d_2)$
Interest rate r	Rho	$\rho = \frac{\partial C}{\partial r} = X \cdot T \cdot e^{-rT} \cdot \Phi(d_2)$

price of the underlying stock. Moreover, an asset manager employing options for risk management wants to know how the value of an option position will change as the price of the underlying changes.

One way to do so is to determine the derivative of the call option price with respect to the spot price of the underlying stock:

$$\Delta = \frac{\partial C}{\partial S} = \Phi(d_1) \tag{5}$$

This quantity is called the “delta” of the option, and can be used in the following way to determine the expected price change in the option if the stock increases by about \$1:

$$\Delta C = C(S + \$x) - C(S) \approx \frac{\partial C}{\partial S} \Delta S = \$x\Phi(d_1) \tag{6}$$

The relation given by (6) holds true for small changes in the price of the underlying. For large changes the assumed linear relationship between call and option price is not valid and we must apply a so-called convexity adjustment:

$$\Delta C = C(S + \$x) - C(S) \approx \frac{\partial C}{\partial S} \$x + \frac{1}{2} \cdot \underbrace{\frac{\partial^2 C}{\partial S^2}}_{=\Gamma} (\$x)^2$$

Here, Γ denotes the “options gamma,” which measures the curvature of the option price as a function of the price of the underlying stock.

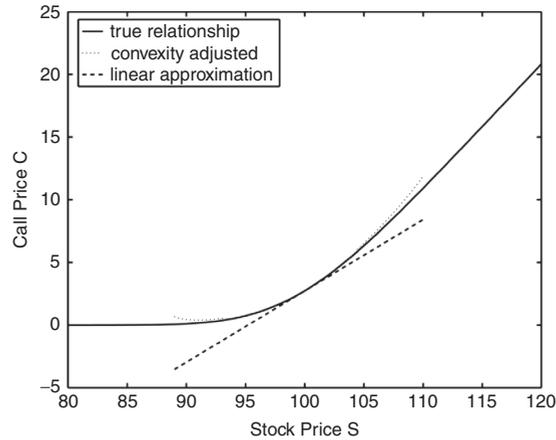

Figure 2 Accuracy of Simple Delta Approximation and Convexity-Adjusted Approximation
Note: The example is calculated for a one-month option with strike $X = \$100$ and current stock price $S = \$100$ with an interest of 10% per annum and volatility of 20% per annum.

Figure 2 visualizes this effect. We see that for small variations in the stock price the “true price” and both approximations nearly coincide. But for medium-sized variations, only the convexity-adjusted approximation is still accurate. For large variations in the underlying stock price both approximations fail.

The impact of the parameters stock price, interest rate, time to maturity, and volatility on the option’s delta is visualized in Figure 3. We can recognize that the influence of a change in the underlying on the option value measured by the option’s delta increases with increasing stock price. Intuitively, this is clear as for large values of the underlying stock the option behaves like the stock itself, whereas for values of the underlying stock near zero, the option is virtually worthless. Also, we can see that if the option is at the money, the impact of a change in the value of the underlying stock increases with increasing time to maturity and with increasing interest rate, which is not as obvious. The delta of the option that is at the money decreases with increasing volatility. The reason is as follows. Imagine that you possess an option on an underlying which is virtually nonrandom.

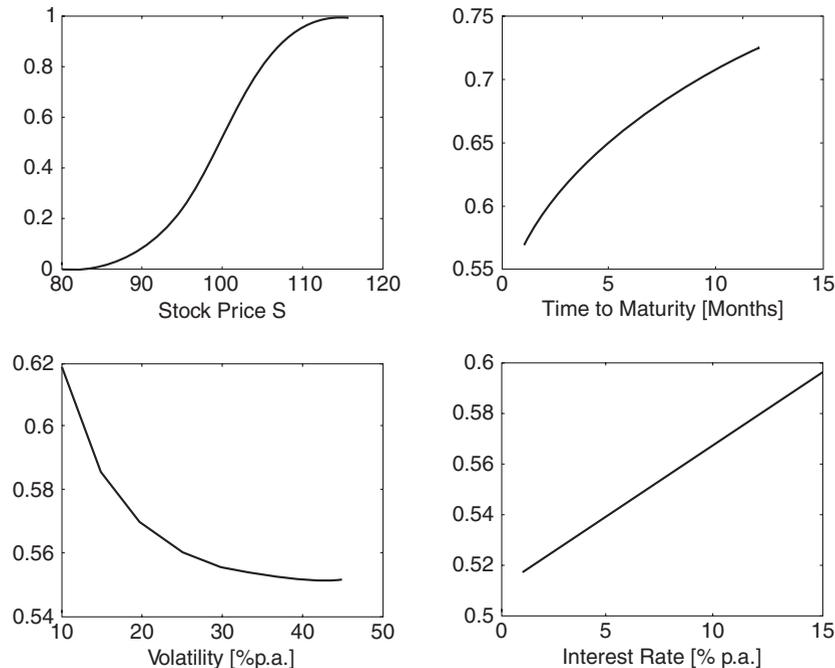

Figure 3 Delta as a Function of the Parameters

Note: The example is calculated for a one-month option with strike $X = \$100$ and current stock price $S = \$100$ with an interest of 10% per annum and a volatility of 20% per annum.

In this case, the value of the option equals its intrinsic value and therefore a change in the underlying stock price has a large impact on the value of the option provided that the current stock price is above the strike. In a stochastic environment (that is, nonzero volatility), every movement of the stock can be immediately followed by a movement in the opposite direction. This is why the option price is not as sensitive to stock price movements when volatility is high (that is, delta decreases with increasing volatility).

For gamma, it is clear that the impact of a change in the price of the underlying is the highest if the option is at the money. If the option is far out or far in the money, we have $C \approx 0$ or $C \approx S$ and, therefore, the second derivative with respect to S will vanish.

Below we will give a brief overview of the remaining sensitivity measures called theta, vega, and rho. Figure 4 visualizes the effect of the cur-

rent stock price on the Greeks gamma, theta, rho, and vega.

The Call Option Price and Time to Expiration: Theta

All other factors constant, the longer the time to expiration, the greater the option price. Since each day the option moves closer to the expiration date, the time to expiration decreases. The theta of an option measures the change in the option price as the time to expiration decreases, or equivalently, it is a measure of time decay.

Assuming that the price of the underlying stock does not change (which means that the intrinsic value of the option does not change), theta measures how quickly the time value of the option changes as the option moves toward expiration.

Buyers of options prefer a low theta so that the option price does not decline quickly as it

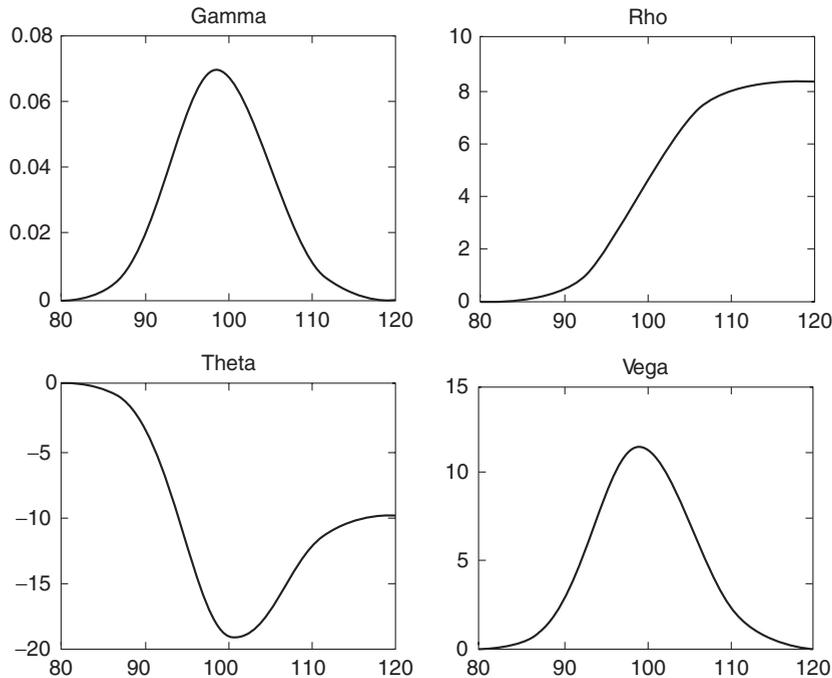

Figure 4 Variation of the Greeks with Respect to the Current Price of the Underlying Stock
Note: The example is calculated for a one-month option with strike $X = \$100$ and spot price $S = \$100$ with an interest of 10% per annum and a volatility of 20% per annum.

moves toward the expiration date. An option writer benefits from an option that has a high theta.

Option Price and Expected Volatility: Vega

All other factors constant, a change in the expected volatility will change the option price. The vega (also called “kappa”) of an option measures the dollar price change in the price of the option for a 1% change in the expected price volatility. (Vega is not a Greek letter. Vega is used to denote *volatility*, just as theta is used for *time* and rho is used for *interest rate*.) The option price is most sensitive with respect to a change in volatility when the option is at or near the money. This can be easily understood as follows. Imagine the option is very deep out of the money (that is, the option is virtually worthless). In this case, any small change in the volatility of the underlying will have no impact on the option price. It will still be nearly zero.

The same holds true if the option is far in the money (that is, it is nearly sure that the option will end in the money and the price of the option equals nearly the price of the stock). In this case, the impact of a small change in the volatility of the stock is negligible as well and, therefore, vega will be small. The situation is different if the option ranges near at the money. In this case, the option is very sensitive to volatility changes as they change the probability of ending in or out of the money dramatically. That is why we have a high vega for an option near the money.

Call Option Price and Interest Rate: Rho

The sensitivity of the option price to a change in the interest rate is called “rho.” The option’s rho is the least popular among the Greeks. Nevertheless, it is of practical value as it can be used to immunize a trader’s position against interest rate risk. An equivalent concept which might be familiar to some readers is the duration of

a bond. For our purposes, rho plays a minor role, and we have introduced it for the sake of completeness.

The Greeks and Portfolio Applications

In practical applications, the Greeks are used to hedge portfolios with respect to certain risk exposures. Because a portfolio is a linear combination of assets and as the derivative of a linear combination of functions equals the linear combination of the derivatives, we can simply calculate the Greek of a portfolio of options or other assets as the linear combination of the individual Greeks. When we seek to build a portfolio in a way that one or several of the Greeks equal zero, then the portfolio is said to be hedged with respect to the respective risk factor. A zero-delta portfolio, for example, is insensitive with respect to small changes in the value of S , and similarly for the other factors.

COMPUTING A PUT OPTION PRICE

We have focused our attention on call options. How do we value put options? This is done by using the following *put-call parity* relationship, which gives the relationship among the price of the common stock, the call option price, and the put option price. By simple no-arbitrage considerations, it can be shown that the following price identity must hold true for a European call and put option with the same strike and maturity:

$$\begin{aligned} \text{Call price} - \text{Put price} &= \text{Stock price} \\ &\quad - \text{Present value of dividends} \\ &\quad - \text{Present value of the strike} \end{aligned}$$

If we can calculate the fair value of a call option, the fair value of a put with the same strike price and expiration on the same stock can be calculated from the put-call parity relationship.

ASSUMPTIONS UNDERLYING THE BLACK-SCHOLES MODEL AND BASIC EXTENSIONS

The Black-Scholes model is based on several restrictive assumptions. These assumptions were necessary to develop the hedge to realize riskless arbitrage profits if the market price of the call option deviates from the price obtained from the model. Here, we will look at these assumptions and mention some basic extensions of the model that make pricing more realistic.

Taxes and Transactions Costs

The Black-Scholes model ignores taxes and transactions costs. The model can be modified to account for taxes, but the problem is that there is not one unique tax rate. Transactions costs include both commissions and the bid-ask spreads for the stock and the option, as well as other costs associated with trading options. This assumption, together with the next two, is the most important for the validity of the Black-Scholes model. The derivation of the price depends mainly on the existence of a replicating portfolio. When transaction costs exist, even if they are negligibly small, then the hedge portfolio can no longer be built and the argument leading to the uniqueness of the price fails.

Trading in Continuous Time, Short Selling, and Trading Arbitrary Fractions of Assets

One crucial assumption underlying the Black-Scholes model is the opportunity to (1) perform trades in continuous time; (2) buy a negative number of all traded assets (short selling); and (3) buy and sell arbitrary fractions of all traded assets. Only these more or less unrealistic assumptions together with the previously discussed absence of transaction costs and taxes allow the derivation of the unique call option

price by the hedging argument. The portfolio, consisting of certain fractions of the bond and the underlying stock, needs an ongoing rebalancing that is only possible in a market that allows continuous-time trading. Additionally, the number of stocks and bonds needed in the portfolio to replicate the option can be an arbitrary real number, possibly negative.

Variance of the Stock's Return

The Black-Scholes model assumes that the variance of the stock's return is (1) constant over the life of the option and (2) known with certainty. If (1) does not hold, an option pricing model can be developed that allows the variance to change. The violation of (2), however, is more serious. As the Black-Scholes model depends on the riskless hedge argument and, in turn, the variance must be known to construct the proper hedge, if the variance is not known, the hedge will not be riskless.

Stochastic Process Generating Stock Prices

To derive an option pricing model, an assumption is needed about the way stock prices move. The Black-Scholes model is based on the assumption that stock prices are generated by a geometric Brownian motion. Geometric Brownian motion is a stochastic process with continuous paths. In reality, one can sometimes observe that the market exhibits large fluctuations that cannot be explained by a continuous-time process with constant volatility as the Brownian motion. In theory, there are two possibilities to overcome this problem. Either one introduces the previously mentioned stochastic volatility or one allows for jumps in the stock price.

Risk-Free Interest Rate

In deriving the Black-Scholes model, two assumptions were made about the risk-free inter-

est rate. First, it was assumed that the interest rates for borrowing and lending were the same. Second, it was assumed that the interest rate was constant and known over the life of the option. The first assumption is unlikely to hold because borrowing rates are higher than lending rates. The effect on the Black-Scholes model is that the option price will be bound between the call price derived from the model using the two interest rates. The model can handle the second assumption by replacing the risk-free rate over the life of the option by the geometric average of the period returns expected over the life of the option. Returns on short-term Treasury bills cannot be known with certainty over the long term. Only the expected return is known, and there is a variance around it. The effects of variable interest rates are considered in Merton (1973).

BLACK-SCHOLES MODEL APPLIED TO THE PRICING OF OPTIONS ON BONDS: IMPORTANCE OF ASSUMPTIONS

While the Black-Scholes option pricing model was developed for nondividend paying stocks, it has been applied to options on bonds. We conclude this entry by demonstrating the limitations of applying the model to valuing options on bonds. This allows us to appreciate the importance of the assumptions on option pricing. To do so, let us look at the values that would be derived in a couple of examples.

We know that there are coupon-paying bonds and zero-coupon bonds. In our illustration we will use a zero-coupon bond. The reason is that the original Black-Scholes model was for common stock that did not pay a dividend and so a zero-coupon bond would be the equivalent type of instrument. Specifically, we look at how the Black-Scholes option pricing model would

value a zero-coupon bond with three years to maturity assuming the following:

Strike price = \$88.00

Time remaining to expiration = 2 years

Current bond price = \$83.96

Expected return volatility = Standard deviation
= 10% per annum

Risk-free rate = 6% per annum

The Black-Scholes model would give an option value of \$8.116. There is no reason to suspect that this value generated by the model is incorrect. However, let us change the problem slightly. Instead of a strike price of \$88, let us make the strike price \$100.25. The Black-Scholes option pricing model would give a fair value of \$2.79. Is there any reason to believe this is incorrect? Well, consider that this is a call option on a zero-coupon bond that will never have a value greater than its maturity value of \$100. Consequently, a call option with a strike price of \$100.25 must have a value of zero. Yet, the Black-Scholes option pricing model tells us that the value is \$2.79! In fact, if we assume a higher expected volatility, the Black-Scholes model would give an even greater value for the call option.

Why is the Black-Scholes model off by so much in our illustration? The answer is that there are three assumptions underlying the Black-Scholes model that limit its use in pricing options on fixed income instruments.

The first assumption is that the probability distribution for the underlying asset's prices assumed by the Black-Scholes model permits some probability—no matter how small—that the price can take on any positive value. But in the case of a zero-coupon bond, the price cannot take on a value above \$100. In the case of a coupon bond, we know that the price cannot exceed the sum of the coupon payments plus the maturity value. For example, for a five-year 10% coupon bond with a maturity value of \$100, the price cannot be greater than \$150 (five coupon payments of \$10 plus the maturity value of \$100). Thus, unlike stock prices, bond

prices have a maximum value. The only way that a bond's price can exceed the maximum value is if negative interest rates are permitted. While there have been instances where negative interest rates have occurred outside the United States, users of option pricing models assume that this outcome cannot occur. Consequently, any probability distribution for prices assumed by an option pricing model that permits bond prices to be higher than the maximum bond value could generate nonsensical option prices. The Black-Scholes model does allow bond prices to exceed the maximum bond value (or, equivalently, assumes that interest rates can be negative).

The second assumption of the Black-Scholes model is that the short-term interest rate is constant over the life of the option. Yet the price of an interest rate option will change as interest rates change. A change in the short-term interest rate changes the rates along the yield curve. Therefore, for interest rate options it is clearly inappropriate to assume that the short-term rate will be constant.

The third assumption is that the variance of returns is constant over the life of the option. As a bond moves closer to maturity, its price volatility declines and therefore its return volatility declines. Therefore, the assumption that variance of returns is constant over the life of the option is inappropriate.

KEY POINTS

- The most popular option pricing model is the Black-Scholes model.
- The factors that affect the value of an option include the current price of the asset, the strike price, the short-term risk-free interest rate, the time remaining to the expiration date of the option, and the expected return volatility.
- Option pricing models depend on the assumption regarding the distribution of returns.

- The option price derived from the Black-Scholes option pricing model is “fair” in the sense that if any other price existed in a market where all the assumptions of the Black-Scholes model are satisfied, riskless arbitrage profits can be realized by taking an offsetting position in the underlying asset.
- The sensitivity of the price of an option to a change in the value of a factor that affects the option’s price can be computed for any option pricing model. These sensitivity measures are referred to as the Greeks (delta, gamma, vega, theta, and rho).
- As with any economic model, there are assumptions that are made. When these assumptions are violated, the model value can depart significantly from the true value of the option.
- Using the Black-Scholes option pricing model to value an option on a bond is a good example where the model assumptions are not consistent with the realities of the bond market.

Pricing of Futures/Forwards and Options

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: There are various models that have been proposed to value financial assets in the cash market. Models for valuing derivatives such as futures, forwards, options, swaps, caps, and floors are valued using arbitrage principles. Basically, the price of a derivative is one that does not allow market participants to generate riskless profits without committing any funds. In developing a pricing model for derivatives, the model builder begins with a strategy (or trade) to exploit the difference between the cash price of the underlying asset for a derivative. The market price for the derivative is the cost of the package to replicate the payoff of the derivative.

Derivative instruments play an important role in financial markets as well as commodity markets by allowing market participants to control their exposure to different types of risk. When using derivatives, a market participant should understand the basic principles of how they are valued. While there are many models that have been proposed for valuing financial instruments that trade in the cash (spot) market, the valuation of all derivative models is based on arbitrage arguments. Basically, this involves developing a strategy or a trade wherein a package consisting of a position in the underlying (that is, the underlying asset or instrument for the derivative contract) and borrowing or lending so as to generate the same cash flow profile as the derivative. The value of the package is then equal to the theoretical price of the deriva-

tive. If the market price of the derivative deviates from the theoretical price, then the actions of arbitrageurs will drive the market price of the derivative toward its theoretical price until the arbitrage opportunity is eliminated.

In developing a strategy to capture any mispricing, certain assumptions are made. When these assumptions are not satisfied in the real world, the theoretical price can only be approximated. Moreover, a close examination of the underlying assumptions necessary to derive the theoretical price indicates how a pricing formula must be modified to value specific contracts.

In this entry, how futures, forwards, and options are valued is explained. The valuation of other derivatives such as swaps, caps, and floors is described in other entries.

PRICING OF FUTURES/FORWARD CONTRACTS

The pricing of futures and forward contracts is similar. If the underlying asset for both contracts is the same, the difference in pricing is due to differences in features of the contract that must be dealt with by the pricing model. To understand the differences, we begin with a definition of the two contracts.

A *futures contract* and a *forward contract* are agreements between a buyer and a seller, in which the buyer agrees to take delivery of the underlying at a specified price at some future date and the seller agrees to make delivery of the underlying at the specified price at the same future date. The buyer and the seller of the contract refers to the obligation that the party has in the future since neither party is obligated to transact in the underlying at the time of the trade. The futures price in the case of a futures contract or forward price in the case of a forward contract is the price at which the parties have agreed to transact in the future. The *settlement date* or *delivery date* is the future date when the two parties have agreed to transact (that is, buy or sell the underlying).

Differences between Futures and Forward Contracts

Futures contracts are standardized agreements as to the delivery date (or month) and quality of the deliverable, and are traded on organized exchanges. Associated with every futures exchange is a *clearinghouse*. The clearinghouse plays an important function: It guarantees that both parties to the trade will perform in the future. In the absence of a clearinghouse, the risk that the two parties face is that in the future when both parties are obligated to perform one of the parties will default. This risk faced in any derivative contract is referred to as counterparty risk. The clearinghouse allows the two parties to enter into a trade without

worrying about counterparty risk with respect to the counterparty to the trade. The reason is that after the trade is executed by the parties, the relationship between the two parties is terminated. The clearinghouse interposes itself as the buyer for every sale and the seller for every purchase. Consequently, the two parties to the trade are free to liquidate their positions without involving the original counterparty.

To protect itself against the counterparty risk of both the buyer and seller to the trade, the exchange where the contract is traded requires that when a position is first taken in a futures contract, both parties must deposit a minimum dollar amount per contract. This amount is specified by the exchange and referred to as *initial margin*. The parties have a choice of providing the initial margin in the form of cash or an interest-bearing security such as a Treasury bill. As the price of the futures contract fluctuates each trading day, the value of the equity of each party in the position changes. The equity in a futures margin account is measured by the sum of all margins posted and all daily gains less all daily losses to the account. To further protect itself against counterparty risk, the exchange specifies that the parties satisfy minimum equity positions. *Maintenance margin* is the minimum level that the exchange specifies that a party's equity position may fall as a result of an unfavorable price movement before a party is required to deposit additional margin. *Variation margin* is the additional margin that a party is required to provide in order to bring the equity in the margin account back to its initial margin level. If a party fails to furnish variation margin within 24 hours, the exchange closes the futures position out. Unlike initial margin, variation margin must be in cash rather than an interest-bearing security. Any excess margin in a party's margin account may be withdrawn.

In pricing futures contracts, the potential interim cash flows of futures contracts that are due to variation margin, in the case of adverse price movements, or withdrawal of cash for a party that experiences a favorable price

movement that results in the margin account's having excess margin must be taken into account.

We'll now compare these characteristics of a futures contract to a forward contract. A forward contract is an over-the-counter (OTC) instrument. That is, it is not an exchange-traded product. A forward contract is usually nonstandardized because the terms of each contract are negotiated individually between the parties to the trade. Also, there is no clearinghouse for trading forward contracts, and secondary markets are often nonexistent or extremely thin.

As just explained, futures contracts are marked to market at the end of each trading day. A forward contract may or may not be marked to market, depending on the wishes of the two parties. For example, both parties to a forward contract may be high-credit-quality entities. The parties may feel comfortable with the counterparty risk up to some specified amount and not require margin. Or one party may be satisfied with the high quality of the counterparty but the other party may not. In such cases, the forward contract may call for the marking to market of the position of only one of the counterparties. For a forward contract that is not marked to market, there are no interim cash-flow effects because no additional margin is required.

Other than these differences, which reflect the institutional arrangements in the two markets, most of what we say about the pricing of futures contracts applies equally to the pricing of forward contracts.

Basic Futures Pricing Model

We will illustrate the basic model for pricing futures contracts here. By "basic" we mean that we are extrapolating from the nuances of the underlying for a specific contract. The issues associated with applying the basic pricing model to some of the more popular futures contracts are described in other entries. Moreover, while the model described here is said to be a model

for pricing futures, technically, it is a model for pricing forward contracts with no mark-to-market requirements.

Rather than deriving the formula algebraically, the basic pricing model will be demonstrated using an illustration. We make the following six assumptions for a futures contract that has no initial and variation margin and which the underlying is asset U:

1. The price of asset U in the cash market is \$100.
2. There is a known cash flow for asset U over the life of the futures contract.
3. The cash flow for asset U is \$8 per year paid quarterly (\$2 per quarter).
4. The next quarterly payment is exactly three months from now.
5. The futures contract requires delivery three months from now.
6. The current three-month interest rate at which funds can be lent or borrowed is 4% per year.

The objective is to determine what the futures price of this contract should be. To do so, suppose that the futures price in the market is \$105. Let's see if that is the correct price. We can check this by implementing the following simple strategy:

- Sell the futures contract at \$105.
- Purchase asset U in the cash market for \$100.
- Borrow \$100 for three months at 4% per year (\$1 per quarter).

The purchase of asset U is accomplished with the borrowed funds. Hence, this strategy does not involve any initial cash outlay. At the end of three months, the following occurs

- \$2 is received from holding asset U.
- Asset U is delivered to settle the futures contract.
- The loan is repaid.

This strategy results in the following outcome:

From settlement of the futures contract:

Proceeds from sale of asset U to settle the futures contract	= \$105
Payment received from investing in asset U for three months	<u>= 2</u>
Total proceeds	= \$107

From the loan:

Repayment of principal of loan	= \$100
Interest on loan (1% for three months)	<u>= 1</u>
Total outlay	= \$101
<i>Profit from the strategy</i>	= \$6

The profit of \$6 from this strategy is guaranteed regardless of what the cash price of asset U is three months from now. This is because in the preceding analysis of the outcome of the strategy, the cash price of asset U three months from now never enters the analysis. Moreover, this profit is generated with no investment outlay; the funds needed to acquire asset U are borrowed when the strategy is executed. In financial terms, the profit in the strategy we have just illustrated arises from a riskless arbitrage between the price of asset U in the cash market and the price of asset U in the futures market.

In a well-functioning market, arbitrageurs who could realize this riskless profit for a zero investment would implement the strategy described above. By selling the futures and buying asset U in order to implement the strategy, this would force the futures price down so that at some price for the futures contract, the arbitrage profit is eliminated.

This strategy that resulted in the capturing of the arbitrage profit is referred to as a *cash-and-carry trade*. The reason for this name is that implementation of the strategy involves borrowing cash to purchase the underlying and “carrying” that underlying to the settlement date of the futures contract.

From the cash-and-carry trade we see that the futures price cannot be \$105. Suppose instead that the futures price is \$95 rather than \$105.

Let’s try the following strategy to see if that price can be sustained in the market:

- Buy the futures contract at \$95.
- Sell (short) asset U for \$100.
- Invest (lend) \$100 for three months at 1% per year.

We assume once again that in this strategy that there is no initial margin and variation margin for the futures contract. In addition, we assume that there is no cost to selling the asset short and lending the money. Given these assumptions, there is no initial cash outlay for the strategy just as with the cash-and-carry trade. Three months from now,

- Asset U is purchased to settle the long position in the futures contract.
- Asset U is accepted for delivery.
- Asset U is used to cover the short position in the cash market.
- Payment is made of \$2 to the lender of asset U as compensation for the quarterly payment.
- Payment is received from the borrower of the loan of \$101 for principal and interest.

More specifically, the strategy produces the following at the end of three months:

From settlement of the futures contract:

Price paid for purchase of asset U to settle futures contract	= \$95
Proceeds to lender of asset U to borrow the asset	<u>= 2</u>
Total outlay	= \$97

From the loan:

Principal from loan	= \$100
Interest earned on loan (\$1 for three months)	<u>= 1</u>
Total proceeds	= \$101
<i>Profit from the strategy</i>	= \$4

As with the cash and trade, the \$4 profit from this strategy is a riskless arbitrage profit. This strategy requires no initial cash outlay, but will generate a profit whatever the price of asset U is in the cash market at the settlement date. In real-world markets, this opportunity would lead arbitrageurs to buy the futures contract and short

asset U. The implementation of this strategy would be to raise the futures price until the arbitrage profit disappeared.

This strategy that is implemented to capture the arbitrage profit is known as a *reverse cash-and-carry trade*. That is, with this strategy, the underlying is sold short and the proceeds received from the short sale are invested.

We can see that the futures price cannot be \$95 or \$105. What is the theoretical futures price given the assumptions in our illustration? It can be shown that if the futures price is \$99 there is no opportunity for an arbitrage profit. That is, neither the cash-and-carry trade nor the reverse cash-and-carry trade will generate an arbitrage profit.

In general, the formula for determining the theoretical futures price given the assumptions of the model is:

$$\begin{aligned} &\text{Theoretical futures price} \\ &= \text{Cash market price} + (\text{Cash market price}) \\ &\quad \times (\text{Financing cost} - \text{Cash yield}) \quad (1) \end{aligned}$$

In the formula given by (1), “Financing cost” is the interest rate to borrow funds and “Cash yield” is the payment received from investing in the asset as a percentage of the cash price. In our illustration, the financing cost is 1% and the cash yield is 2%.

In our illustration, since the cash price of asset U is \$100, the theoretical futures price is:

$$\$100 + \$100 \times (1\% - 2\%) = \$99$$

The future price can be above or below the cash price depending on the difference between the financing cost and cash yield. The difference between these rates is called the *net financing cost*. A more commonly used term for the net financing cost is the *cost of carry*, or simply, *carry*. *Positive carry* means that the cash yield exceeds the financing cost. (Note that while the difference between the financing cost and the cash yield is a negative value, carry is said to be positive.) *Negative carry* means that the financing cost exceeds the cash yield. Below is a summary

of the effect of carry on the difference between the futures price and the cash market price:

Positive carry	Futures price will sell at a discount to cash price.
Negative carry	Futures price will sell at a premium to cash price.
Zero	Futures price will be equal to the cash price.

Note that at the settlement date of the futures contract, the futures price must equal the cash market price. The reason is that a futures contract with no time left until delivery is equivalent to a cash market transaction. Thus, as the delivery date approaches, the futures price will converge to the cash market price. This fact is evident from the formula for the theoretical futures price given by (1). The financing cost approaches zero as the delivery date approaches. Similarly, the yield that can be earned by holding the underlying approaches zero. Hence, the cost of carry approaches zero, and the futures price approaches the cash market price.

A Closer Look at the Theoretical Futures Price

In deriving theoretical futures price using the arbitrage argument, several assumptions had to be made. These assumptions as well as the differences in contract specifications will result in the futures price in the market deviating from the theoretical futures price as given by (1). It may be possible to incorporate these institutional and contract specification differences into the formula for the theoretical futures price. In general, however, because it is oftentimes too difficult to allow for these differences in building a model for the theoretical futures price, the end result is that one can develop bands or boundaries for the theoretical futures price. So long as the futures price in the market remains within the band, no arbitrage opportunity is possible.

Next, we will look at some of the institutional and contract specification differences that cause

prices to deviate from the theoretical futures price as given by the basic pricing model.

Interim Cash Flows

In the derivation of a basic pricing model, it is assumed that no interim cash flows arise because of changes in futures prices (that is, there is no variation margin). As noted earlier, in the absence of initial and variation margins, the theoretical price for the contract is technically the theoretical price for a forward contract that is not marked to market rather than a futures contract.

In addition, the model assumes implicitly that any dividends or coupon interest payments are paid at the settlement date of the futures contract rather than at any time between initiation of the cash position and settlement of the futures contract. However, we know that interim cash flows for the underlying for financial futures contracts do have interim cash flows. Consider stock index futures contracts and bond futures contracts.

For a stock index, there are interim cash flows. In fact, there are many cash flows that are dependent upon the dividend dates of the component companies. To correctly price a stock index future contract, it is necessary to incorporate the interim dividend payments. Yet, the dividend rate and the pattern of dividend payments are not known with certainty. Consequently, they must be projected from the historical dividend payments of the companies in the index. Once the dividend payments are projected, they can be incorporated into the pricing model. The only problem is that the value of the dividend payments at the settlement date will depend on the interest rate at which the dividend payments can be reinvested from the time they are projected to be received until the settlement date. The lower the dividend, and the closer the dividend payments to the settlement date of the futures contract, the less important the reinvestment income is in determining the futures price.

In the case of a Treasury futures contract, the underlying is a Treasury note or a Treasury bond. Unlike a stock index futures contract, the timing of the interest payments that will be made by the U.S. Department of the Treasury for a given issue that is acceptable as deliverable for a contract is known with certainty and can be incorporated into the pricing model. However, the reinvestment interest that can be earned from the payment dates to the settlement of the contract is unknown and depends on prevailing interest rates at each payment date.

Differences in Borrowing and Lending Rates

In the formula for the theoretical futures price, it is assumed in the cash-and-carry trade and the reverse cash-and-carry trade that the borrowing rate and lending rate are equal. Typically, however, the borrowing rate is higher than the lending rate. The impact of this inequality is important and easy to quantify.

In the cash-and-carry trade, the theoretical futures price as given by (1) becomes:

$$\begin{aligned} \text{Theoretical futures price based on borrowing rate} \\ = \text{Cash market price} + (\text{Cash market price}) \\ \times (\text{Borrowing rate} - \text{Cash yield}) \end{aligned} \quad (2)$$

For the reverse cash-and-carry trade, it becomes

$$\begin{aligned} \text{Theoretical futures price based on lending rate} \\ = \text{Cash market price} + (\text{Cash market price}) \\ \times (\text{Lending rate} - \text{Cash yield}) \end{aligned} \quad (3)$$

Formulas (2) and (3) together provide a band between which the actual futures price can exist without allowing for an arbitrage profit. Equation (2) establishes the upper value for the band while equation (3) provides the lower value for the band. For example, assume that the borrowing rate is 6% per year, or 1.5% for three months, while the lending rate is 4% per year, or 1% for three months. Using equation (2), the

upper value for the theoretical futures price is \$99.5 and using equation (3) the lower value for the theoretical futures price is \$99.

Transaction Costs

The two strategies to exploit any price discrepancies between the cash market and theoretical price for the futures contract will require the arbitrageur to incur transaction costs. In real-world financial markets, the costs of entering into and closing the cash position as well as round-trip transaction costs for the futures contract affect the futures price. As in the case of differential borrowing and lending rates, transaction costs widen the bands for the theoretical futures price.

Short Selling

The reverse cash-and-strategy trade requires the short selling of the underlying. It is assumed in this strategy that the proceeds from the short sale are received and reinvested. In practice, for individual investors, the proceeds are not received, and, in fact, the individual investor is required to deposit margin (securities margin and not futures margin) to short sell. For institutional investors, the underlying may be borrowed, but there is a cost to borrowing. This cost of borrowing can be incorporated into the model by reducing the cash yield on the underlying. For strategies applied to stock index futures, a short sale of the components stocks in the index means that all stocks in the index must be sold simultaneously. This may be difficult to do and therefore would widen the band for the theoretical future price.

Known Deliverable Asset and Settlement Date

In the two strategies to arbitrage discrepancies between the theoretical futures price and the cash market price, it is assumed that (1) only one asset is deliverable and (2) the settlement date occurs at a known, fixed point in the future. Neither assumption is consistent with the

delivery rules for some futures contracts. For U.S. Treasury note and bond futures contracts, for example, the contract specifies that any one of several Treasury issues that is acceptable for delivery can be delivered to satisfy the contract. Such issues are referred to as deliverable issues. The selection of which deliverable issue to deliver is an option granted to the party who is short the contract (that is, the seller). Hence, the party that is long the contract (that is, the buyer of the contract) does not know the specific Treasury issue that will be delivered. However, market participants can determine the cheapest-to-deliver issue from the issues that are acceptable for delivery. It is this issue that is used in obtaining the theoretical futures price. The net effect of the short's option to select the issue to deliver to satisfy the contract is that it reduces the theoretical future price by an amount equal to the value of the delivery option granted to the short.

Moreover, unlike other futures contracts, the Treasury bond and note contracts do not have a delivery date. Instead, there is a delivery month. The short has the right to select when in the delivery month to make delivery. The effect of this option granted to the short is once again to reduce the theoretical futures price below that given by equation (1). More specifically,

$$\begin{aligned} &\text{Theoretical futures price adjusted for delivery options} \\ &= \text{Cash market price} + (\text{Cash market price}) \\ &\quad \times (\text{Financing cost} - \text{Cash yield}) - \text{Value of the} \\ &\quad \text{delivery options granted to the short} \end{aligned} \quad (4)$$

Deliverable as a Basket of Securities

Some futures contracts have as the underlying a basket of assets or an index. Stock index futures are the most obvious example. At one time, municipal futures contracts were actively traded and the underlying was a basket of municipal securities. The problem in arbitraging futures contracts in which there is a basket of assets or an index is that it may be too expensive to buy or sell every asset included in the basket or index. Instead, a portfolio containing a smaller

number of assets may be constructed to track the basket or index (which means having price movements that are very similar to changes in the basket or index). Nonetheless, the two arbitrage strategies involve a tracking portfolio rather than a single asset for the underlying, and the strategies are no longer risk-free because of the risk that the tracking portfolio will not precisely replicate the performance of the basket or index. For this reason, the market price of futures contracts based on baskets of assets or an index is likely to diverge from the theoretical price and have wider bands.

Different Tax Treatment of Cash and Futures Transaction

Participants in the financial market cannot ignore the impact of taxes on a trade. The strategies that are implemented to exploit arbitrage opportunities between prices in the cash and futures markets and the resulting pricing model must recognize that there are differences in the tax treatment under the tax code for cash and futures transactions. The impact of taxes must be incorporated into the pricing model.

PRICING OF OPTIONS

Now we will look at the basic principles for valuing options. There are two parties to an option contract: the buyer and the writer or seller. The writer of the option grants the buyer of the option the right, but not the obligation, to either purchase from or sell to the writer something at a specified price within a specified period of time (or at a specified date). In exchange for the right that the writer grants the buyer, the buyer pays the writer a certain sum of money. This sum is called the option price or option premium. The price at which the underlying may be purchased or sold is called the *exercise price* or *strike price*. The option's *expiration date* (or maturity date) is the last date at which the option buyer can exercise the option. After the

expiration date, the contract is void and has no value.

There are two types of options: call options and put options. A *call option*, or simply call, is one in which the option writer grants the buyer the right to purchase the underlying. When the option writer grants the buyer the right to sell the underlying, the option is called a *put option*, or simply, a put.

The timing of the possible exercise of an option is an important characteristic of an option contract. An *American option* allows the option buyer to exercise the option at any time up to and including the expiration date. A *European option* allows the option buyer to exercise the option only on the expiration date.

As with futures and forward contracts, the theoretical price of an option is also derived based on arbitrage arguments. However, as will be explained, the pricing of options is not as simple as the pricing of futures and forward contracts.

Basic Components of the Option Price

The theoretical price of an option is made up of two components: the intrinsic value and a premium over intrinsic value.

Intrinsic Value

The *intrinsic value* is the option's economic value if it is exercised immediately. If no positive economic value would result from exercising immediately, the intrinsic value is zero. An option's intrinsic value is easy to compute given the price of the underlying and the strike price.

For a call option, the intrinsic value is the difference between the current market price of the underlying and the strike price. If that difference is positive, then the intrinsic value equals that difference; if the difference is zero or negative, then the intrinsic value is equal to zero. For example, if the strike price for a call option is \$100 and the current price of the underlying

is \$109, the intrinsic value is \$9. That is, an option buyer exercising the option and simultaneously selling the underlying would realize \$109 from the sale of the underlying, which would be covered by acquiring the underlying from the option writer for \$100, thereby netting a \$9 gain.

An option that has a positive intrinsic value is said to be *in-the-money*. When the strike price of a call option exceeds the underlying's market price, it has no intrinsic value and is said to be *out-of-the-money*. An option for which the strike price is equal to the underlying's market price is said to be *at-the-money*. Both at-the-money and out-of-the-money options have intrinsic values of zero because it is not profitable to exercise them. Our call option with a strike price of \$100 would be (1) in the money when the market price of the underlying is more than \$100; (2) out of the money when the market price of the underlying is less than \$100, and (3) at the money when the market price of the underlying is equal to \$100.

For a put option, the intrinsic value is equal to the amount by which the underlying's market price is below the strike price. For example, if the strike price of a put option is \$100 and the market price of the underlying is \$95, the intrinsic value is \$5. That is, the buyer of the put option who simultaneously buys the underlying and exercises the put option will net \$5 by exercising. The underlying will be sold to the writer for \$100 and purchased in the market for \$95. With a strike price of \$100, the put option would be (1) in the money when the underlying's market price is less than \$100, (2) out of the money when the underlying's market price exceeds \$100, and (3) at the money when the underlying's market price is equal to \$100.

Time Premium

The *time premium* of an option, also referred to as the time value of the option, is the amount by which the option's market price exceeds its intrinsic value. It is the expectation of the option buyer that at some time prior to the ex-

piration date changes in the market price of the underlying will increase the value of the rights conveyed by the option. Because of this expectation, the option buyer is willing to pay a premium above the intrinsic value. For example, if the price of a call option with a strike price of \$100 is \$12 when the underlying's market price is \$104, the time premium of this option is \$8 (\$12 minus its intrinsic value of \$4). Had the underlying's market price been \$95 instead of \$104, then the time premium of this option would be the entire \$12 because the option has no intrinsic value. All other things being equal, the time premium of an option will increase with the amount of time remaining to expiration.

An option buyer has two ways to realize the value of an option position. The first way is by exercising the option. The second way is to sell the option in the market. In the first example above, selling the call for \$12 is preferable to exercising, because the exercise will realize only \$4 (the intrinsic value), but the sale will realize \$12. As this example shows, exercise causes the immediate loss of any time premium. It is important to note that there are circumstances under which an option may be exercised prior to the expiration date. These circumstances depend on whether the total proceeds at the expiration date would be greater by holding the option or exercising and reinvesting any received cash proceeds until the expiration date.

Put-Call Parity Relationship

For a European put and a European call option with the same underlying, strike price, and expiration date, there is a relationship between the price of a call option, the price of a put option, the price of the underlying, and the strike price. This relationship is known as the *put-call parity relationship*. The relationship is:

$$\begin{aligned} \text{Put option price} - \text{Call option price} &= \text{Present value} \\ &\text{of strike price} + \text{Present value of cash distribution} \\ &- \text{Price of underlying} \end{aligned}$$

Factors That Influence the Option Price

The factors that affect the price of an option include the:

- Market price of the underlying.
- Strike price of the option.
- Time to expiration of the option.
- Expected volatility of the underlying over the life of the option.
- Short-term, risk-free interest rate over the life of the option.
- Anticipated cash payments on the underlying over the life of the option.

The impact of each of these factors may depend on whether (1) the option is a call or a put, and (2) the option is an American option or a European option. Table 1 summarizes how each of the six factors listed above affects the price of a put and call option. Here, we briefly explain why the factors have the particular effects.

Market Price of the Underlying Asset

The option price will change as the price of the underlying changes. For a call option, as the underlying's price increases (all other factors being constant), the option price increases. The opposite holds for a put option: As the price of the underlying increases, the price of a put option decreases.

Table 1 Summary of Factors That Affect the Price of an Option

Factor	Effect of an Increase of Factor On	
	Call Price	Put Price
Market price of underlying	Increase	Decrease
Strike price	Decrease	Increase
Time to expiration of option	Increase	Increase
Expected volatility	Increase	Increase
Short-term, risk-free interest rate	Increase	Decrease
Anticipated cash payments	Decrease	Increase

Strike Price

The strike price is fixed for the life of the option. All other factors being equal, the lower the strike price, the higher the price for a call option. For put options, the higher the strike price, the higher the option price.

Time to Expiration of the Option

After the expiration date, an option has no value. All other factors being equal, the longer the time to expiration of the option, the higher the option price. This is because, as the time to expiration decreases, less time remains for the underlying's price to rise (for a call buyer) or fall (for a put buyer), and therefore the probability of a favorable price movement decreases. Consequently, as the time remaining until expiration decreases, the option price approaches its intrinsic value.

Expected Volatility of the Underlying over the Life of the Option

All other factors being equal, the greater the expected volatility (as measured by the standard deviation or variance) of the underlying, the more the option buyer would be willing to pay for the option, and the more an option writer would demand for it. This occurs because the greater the expected volatility, the greater the probability that the movement of the underlying will change so as to benefit the option buyer at some time before expiration.

Short-Term, Risk-Free Interest Rate over the Life of the Option

Buying the underlying requires an investment of funds. Buying an option on the same quantity of the underlying makes the difference between the underlying's price and the option price available for investment at an interest rate at least as high as the risk-free rate. Consequently, all other factors being constant, the higher the short-term, risk-free interest rate, the

greater the cost of buying the underlying and carrying it to the expiration date of the call option. Hence, the higher the short-term, risk-free interest rate, the more attractive the call option will be relative to the direct purchase of the underlying. As a result, the higher the short-term, risk-free interest rate, the greater the price of a call option.

Anticipated Cash Payments on the Underlying over the Life of the Option

Cash payments on the underlying tend to decrease the price of a call option because the cash payments make it more attractive to hold the underlying than to hold the option. For put options, cash payments on the underlying tend to increase the price.

Option Pricing Models

Earlier in this entry, it was explained how the theoretical price of a futures contract and forward contract can be determined on the basis of arbitrage arguments. An option pricing model uses a set of assumptions and arbitrage arguments to derive a theoretical price for an option. Deriving a theoretical option price is much more complicated than deriving a theoretical futures or forward price because the option price depends on the expected volatility of the underlying over the life of the option.

Several models have been developed to determine the theoretical price of an option. The most popular one was developed by Fischer Black and Myron Scholes (1973) for valuing European call options on common stock. The Black-Scholes model requires as input the six factors discussed above that affect the value of an option. Several modifications to the Black-Scholes model followed. One such model is the lattice model suggested by Cox, Ross, and Rubinstein (1979), Rendleman and Bartter (1979), and Sharpe (1981).

Basically, the idea behind the arbitrage argument is that if the payoff from owning a call option can be replicated by (1) purchasing the underlying for the call option and (2) borrowing funds to purchase the underlying, then the cost of creating the replicating strategy (position) is the theoretical price of the option.

KEY POINTS

- For futures and forward contracts, the theoretical price can be derived using arbitrage arguments. Specifically, a cash-and-carry trade can be implemented to capture the arbitrage profit for an overpriced futures or forward contract while a reverse cash-and-carry trade can be implemented to capture the arbitrage profit for an underpriced futures or forward contract.
- The basic model states that the theoretical futures price is equal to the cash market price plus the net financing cost. The net financing cost, also called the cost of carry, is the difference between the financing cost and the cash yield on the underlying.
- Because of institutional and contract specification differences, the market price for the futures or forward contract can deviate from the theoretical price without any arbitrage opportunities being possible. Basically, a band can be established for the theoretical futures price and as long as the market price for the futures contract is not outside of the band, there is no arbitrage opportunity.
- The two components of the price of an option are the intrinsic value and the time premium. The former is the economic value of the option if it is exercised immediately, while the latter is the amount by which the option price exceeds the intrinsic value.
- The option price is affected by six factors: (1) the market price of the underlying; (2) the strike price of the option; (3) the time

remaining to the expiration of the option; (4) the expected volatility of the underlying as measured by the standard deviation; (5) the short-term, risk-free interest rate over the life of the option; and (6) the anticipated cash payments on the underlying.

- It is the uncertainty about the expected volatility of the underlying that makes valuing options more complicated than valuing futures and forward contracts.
- There are various models for determining the theoretical price of an option. These include the Black-Scholes model and the lattice model.

Pricing Options on Interest Rate Instruments

RADU TUNARU, PhD

Professor of Quantitative Finance, Business School, University of Kent

BRIAN EALES

Academic Leader (Retired), London Metropolitan University

Abstract: Interest rate modeling has quickly become one of the main areas in financial markets. The models have grown in sophistication in response to development of new products and structures. Almost all pricing of securities and the risk management function, including marking-to-market, relies on interest rate modeling of some description. The information on interest rates, usually conveyed from the options markets, is important for other markets as well, such as the more established credit risk, commodities, equities, and the more recent ones such as inflation derivatives and insurance derivatives. Many models have been developed over the years, and their advantages and disadvantages should be appreciated and understood when they are applied.

Throughout the world, *interest rates* serve as instruments of control. When inflation rises to an undesirable or politically unacceptable level, the appropriate authorities raise interest rates to curb expenditure. In times when economic activity and corporate and consumer confidence is less buoyant, the policy is to lower rates. Interest rate derivatives were among the first contracts to be offered on derivative exchanges and have their origins in the period following the breakdown of the Bretton Woods Agreement. In today's sometimes volatile markets, they continue to be extremely useful tools for corporates, banks, and individuals from hedging, financial engineering, and speculative perspectives.

Two of the early prime movers in the interest rate derivatives market were the Chicago Board

of Trade (CBOT) and the Chicago Mercantile Exchange (CME). (In July 2007 the CBOT and CME merged to form the CME group.) Some of the contracts that were introduced in the 1970s are still popular today, as evidenced by the high volume they enjoy.

At the short end of the yield curve, the CME has the world's most actively traded exchange-based interest rate option contracts: Eurodollar options. Each Eurodollar option has as its underlying a Eurodollar time deposit futures contract with a principal value of \$1 million, which will be cash settled at maturity. Another high-volume contract available on the CME is the option on the one-month Eurodollar futures contract. This, too, is cash settled at maturity.

CME also, has option contracts on U.S. Treasury bonds and notes in its portfolio of interest rate derivative products. There are American-style options available on bonds with a maturity of at least 25-years, between 15 but less than 25 years, 10-year, 5-year, 3-year and 2-year notes, the most heavily traded of which is the 10-year Treasury note. The option contract has as its deliverable one U.S. Treasury 10-year note futures contract with a face value of \$100,000 at maturity. Whereas the CME futures contracts on short-term interest rates are cash settled, the bond/note futures require physical settlement. The corresponding option contracts have similar settlement requirements identified in their contract specifications. The CME Group lists seven international data vendors who provided quotes for call/put options across a range of strike prices and maturities.

Although option prices are easy to read and interpret from vendor screens, there is a mass of academic and practitioner research literature, which provides a platform from which *bond option prices* in general can be calculated with integrity. The literature on modeling interest rate derivatives in this arena is frequently divided into one- or two-factor (or multifactor) models.

- Calculating option prices in a one-factor model usually proposes that the process is driven by the short rate, often with a mean-reversion feature linked to the short rate. There are several popular models that fall into this category, for example, the *Vasicek model* and the Cox, Ingersoll, and Ross (CIR) model, both of which will be discussed in more detail later.
- Calculating option prices in a two-factor model involves both the short- and long-term rates linked by a mean-reversion process.

The problem with some of the preceding models is that they generate their own term structures, which, in the absence of adjustment, do not match the term structure observed in the market. A category of arbitrage-free models proposed by Ho and Lee (1986); Hull and White

(1990); and Black, Derman, and Toy (1990) seeks to eliminate this problem. For example, the Black, Derman, and Toy model enjoys a degree of popularity among market practitioners, since it takes account of and matches the term structure observed in the market, it eliminates the possibility of generating negative interest rates, and it models the observed interest rate volatility. These models together with other propositions will be discussed in more detail in this entry.

In order to examine some of the major developments in option/derivative pricing in the interest rate field, it is appropriate at this point to establish a working framework.

MODELING THE TERM STRUCTURE AND BOND PRICES

Let $(\Omega, \Sigma, \{F_t\}_{t \geq 0}, Q)$ be a filtered probability space modeling a financial market, where the filtration $F = \{F_t\}_{t \geq 0}$ describes the flux of information and the probability measure Q denotes the risk-neutral measure; the real-world or physical measure will be denoted by P . The starting point in modeling bond prices is the assumption that there is a bank account $B = \{B(t)\}_{t \geq 0}$ that is linked to the bank instantaneous interest rate (also called short rate, spot rate) process $r = \{r(t)\}_{t \geq 0}$ through

$$dB(t) = r(t)B(t)dt \quad \text{or} \\ B(t) = B(0) \exp \left[\int_0^t r(s)ds \right] \quad (1)$$

From a practical point of view, we can safely assume that the majority of stochastic processes representing prices of traded financial assets are adapted to the filtration F and that the short-rate process $r = \{r(t)\}_{t \geq 0}$ is a predictable process, meaning that $r(t)$ is F_{t-1} measurable. This implies that $B(t)$ is also F_{t-1} measurable and this condition is automatically satisfied for continuous or left-continuous processes.

In this entry we consider only default-free securities. We shall denote by $p(t, T)$ the price at time t of a pure discount bond with maturity T and obviously $p(t, t) = p(T, T) = 1$.

The following relationships are well known in the fixed-income area:

$$0 < p(t, T) \leq 1, \quad r(t) = \frac{\partial \ln p(t, T)}{\partial t} \Big|_{T=t}$$

$$= - \frac{\partial \ln p(t, T)}{\partial T} \Big|_{T=t}, \quad \text{for any } t < T \quad (2)$$

Let $f(t, s)$ be the *forward rate* at time $s > 0$ calculated at time $t < s$. The instantaneous forward rate at time t to borrow at time T can be calculated from the bond prices using

$$f(t, T) = - \frac{\partial \ln p(t, T)}{\partial T} \quad (3)$$

The reverse works as well; if forward rates are known, then bond prices can be calculated via $p(t, T) = e^{-\int_t^T f(t, s) ds}$. The short rate is intrinsically related to the forward rates because $r(t) \equiv f(t, t)$.

Short-Rate Models of Term Interest Rate Structure

Many models proposed for the short-rate process $r = \{r(t)\}_{t \geq 0}$ are particular cases of the general diffusion equation:

$$dr(t) = a(t, r(t))dt + b(t, r(t))dW(t) \quad (4)$$

where $W = \{W(t)\}_{t \geq 0}$ is a standard Wiener process defined on $(\Omega, \Sigma, \{F_t\}_{t \geq 0}, Q)$. The following list of models describes a chronological evolution without claiming that it is an exhaustive list:

The Merton model (Merton, 1973) is

$$dr(t) = \alpha dt + \sigma dW(t) \quad (5)$$

The Vasicek model (Vasicek, 1977) model is

$$dr(t) = (\alpha - \beta r(t))dt + \sigma dW(t) \quad (6)$$

One advantage of the Vasicek model is that the conditional distribution of r at any future time, given the current interest rates at time t , is

normally distributed. The main moments are

$$E_t(r(s)) = \frac{\alpha}{\beta} + \left(r(t) - \frac{\alpha}{\beta} \right) e^{-\beta(s-t)}, \quad t \leq s$$

$$\text{var}_t[r(s)] = \frac{\sigma^2}{2\beta} (1 - e^{-2\beta(s-t)}), \quad t \leq s \quad (7)$$

$$\text{cov}_t[r(u), r(s)] = \frac{\sigma^2}{2\beta} e^{-\beta(s+u-2t)} (e^{2\beta(u-t)} - 1),$$

$$t \leq u \leq s$$

Another advantage is that this model can be also derived within a general equilibrium framework as illustrated by Campbell (1986).

One disadvantage that is often discussed in the *interest rate modeling* literature is that there is a long-run possibility of negative interest rates. However, Rabinovitch (1989) proved that when the initial interest rate $r(0)$ is positive and the parameter estimates have reasonable values, the expected first-passage time of the process through the origin is longer than nine months. This result supports the use of the Vasicek model in practice since the majority of options traded on the organized exchanges expire in less than nine months.

The Dothan model (Dothan, 1978) is

$$dr(t) = \alpha r(t)dt + \sigma r(t)dW(t) \quad (8)$$

This is the same model as Rendleman and Bartter's model (Rendleman and Bartter, 1980). This model is the only lognormal single-factor model that leads to closed formulae for pure discount bonds. Nonetheless, there is no closed formula for a European option on a pure discount bond.

The *Cox-Ingersoll-Ross (CIR) models* (Cox, Ingersoll, and Ross, 1980, 1985) are

$$dr(t) = \beta(r(t))^{3/2}dW(t)$$

$$dr(t) = (\alpha - \beta r(t))dt + \sigma(r(t))^{1/2}dW(t) \quad (9)$$

CIR wrote arguably the first of several papers developing one-factor models of the term structure of interest rates. Around the same time models in the same spirit include the Vasicek, Dothan, Courtadon (1982), and Brennan and Schwartz (1979) models. The movements of

longer-maturity instruments are perfectly correlated with the instantaneous short-term rates.

The Ho-Lee model (Ho and Lee, 1986) is

$$dr(t) = \alpha(t)dt + \sigma dW(t) \quad (10)$$

This is the continuous version of the original model that was probably the first model designed to match exactly the observable term structure of interest rates.

The Black-Derman-Toy (BDT) model (Black, Derman, and Toy, 1990) is

$$dr(t) = \alpha(t)r(t)dt + \sigma(t)dW(t) \quad (11)$$

The Hull-White (HW) models (Hull and White, 1990, 1994, 1996) are

$$\begin{aligned} dr(t) &= [\alpha(t) - \beta(t)r(t)]dt + \sigma(t)dW(t) \\ dr(t) &= [\alpha(t) - \beta(t)r(t)]dt + \sigma(t)(r(t))^{1/2}dW(t) \end{aligned} \quad (12)$$

These models are two more general families of models incorporating the Vasicek model and CIR model, respectively. The first one is more often used and it can be calibrated to the observable term structure of interest rates and the volatility term structure of spot or forward rates. However, its implied volatility structures may be unrealistic. Hence, it may be wise to use a constant coefficient $\beta(t) = \beta$ and a constant volatility parameter $\sigma(t) = \sigma$ and then calibrate the model using only the term structure of market interest rates. It is still theoretically possible that the short rate r may go negative. The risk-neutral probability for the occurrence of such an event is

$$Q(r(t) < 0) = N\left(-\frac{\tilde{f}(0, t) + \frac{\sigma^2}{2\beta^2}(1 - e^{\beta t})^2}{\sqrt{\frac{\sigma^2}{2\beta^2}(1 - e^{2\beta t})}}\right) \quad (13)$$

where $\tilde{f}(0, t)$ is the market instantaneous forward rate. In practice, this probability seems to be rather small, as empirical evidence illustrated by Brigo and Mercurio (2007) shows. However, the probability is not zero, and this may bother some analysts.

An example will provide an idea of how a variation of one of the models proposed by Hull

and White described above by the first of (12) models can be used to price an option on a zero-coupon bond. If the assumptions are made that both β , the reversion rate, and σ , volatility, are constant, then the model can be restated as:

$$dr(t) = [\alpha(t) - \beta r(t)]dt + \sigma dW(t) \quad (14)$$

and the function $\alpha(t)$ can be calculated from a given term structure using:

$$\alpha(t) = f_T(0, t) + \beta f(0, t) + \frac{\sigma^2}{2\beta}(1 - e^{-2\beta t}) \quad (15)$$

The future market price of a zero-coupon bond in this framework can be found by defining the reversion rate, β , the volatility, and the time period involved.

$$p(T_0, T) = A(T_0, T)e^{-B(T_0, T)r(T_0)} \quad (16)$$

where T_0 represents the forward date at which the bond is to be priced, T represents the bond's maturity date, t is a time period index typically taken to be equal to zero (that is, representing the current point in time)

$$B(T_0, T) = \frac{1}{\beta}(1 - e^{-\beta(T-T_0)}) \quad (17)$$

$$\begin{aligned} \ln A(T_0, T) &= \ln\left(\frac{p(t, T)}{p(t, T_0)}\right) \\ &\quad - B(T_0, T) \frac{\partial \ln p(t, T_0)}{\partial T} \\ &\quad - \frac{1}{4\beta^3} \sigma^2 \left(e^{-\beta(T-t)} - e^{-\beta(T_0-t)}\right)^2 \\ &\quad \times \left(e^{2\beta(T_0-t)} - 1\right) \end{aligned} \quad (18)$$

and $r(T)$ is the prevailing short rate at the forward date.

To illustrate how this works consider the case where we wish to find the 1-year forward price of a bond with 4 years remaining to maturity. Assume that the yield curve offers 4.00% continuously compounded for all maturities, volatility is 2.00%, and the reversion rate is 0.1. In this example T is 4 and T_0 is 1. The price of the bond can be found using $p(1, 4) = A(1, 4)e^{-B(1, 4)(0.04)}$. Clearly, $A(1, 4)$ and $B(1, 4)$

must be evaluated. Starting with $B(1,4)$ we have $B(1, 4) = \frac{1}{0.1} (1 - e^{-0.1(4-1)}) = 2.5918 \dots$

The next step requires the evaluation of $A(1, 4)$ and the expression for $\ln A(1, 4)$ can be broken down into a series of relatively straightforward calculations:

$$\begin{aligned} \ln \left(\frac{p(t, T)}{p(t, T_0)} \right) &= \ln \left(\frac{p(0, 4)}{p(0, 1)} \right) = \ln \left(\frac{e^{-(4)(0.04)}}{e^{-(1)(0.04)}} \right) \\ &= \ln \left(\frac{0.8521}{0.9607} \right) = -0.12 \end{aligned}$$

$B(1, 4)$ has already been calculated and is equal to 2.5918. Moreover, $\frac{\partial \ln p(t, T_0)}{\partial T_0}$ can be approximated by $\left(\frac{\ln p(t, T_0 + \Delta t) - \ln p(t, T_0 - \Delta t)}{2\Delta t} \right)$ which, if a time interval, Δt , is assumed to be 0.1 years yields $\left(\frac{\ln p(0, 1 + 0.1) - \ln p(0, 1 - 0.1)}{2(0.1)} \right) = -0.04$. This leaves the expression:

$$\begin{aligned} &\frac{1}{4\beta^3} \sigma^2 \left(e^{-\beta(T-t)} - e^{-\beta(T_0-t)} \right)^2 \left(e^{2\beta(T_0-t)} - 1 \right) \\ &= \frac{1}{4(0.1)^3} 0.02^2 \left(e^{-(0.1)(4)} - e^{-(0.1)(1)} \right)^2 \\ &\quad \times \left(e^{2(0.1)(1)} - 1 \right) = 0.001217 \end{aligned}$$

Combining all the above calculations we find $\ln A(1, 4) = -0.01754$ and then the one-year forward bond price is $p(1, 4) = e^{-0.01754 \dots - 2.5918 \dots (0.04)} = 0.8858$.

The Black-Karasinski (BK) model (Black and Karasinski, 1991) is

$$dr(t) = r(t)[\alpha(t) - \beta(t) \ln r(t)]dt + \sigma(t)r(t)dW(t) \tag{19}$$

The BDT, HW, and BK models extended the Ho-Lee model to match a term structure volatility curve (e.g., the *cap* prices) in addition to the term structure. The BK model is a generalization of the BDT model, and it overcomes the problem of negative interest rates, assuming that the short rate r is the exponential of an OU process having time-dependent coefficients. It is popular with practitioners because it fits well the swaption volatility surface. Nevertheless, it does not have closed formulae for bonds or options on bonds.

The Sandmann-Sondermann model (Sandmann and Sondermann, 1993) is

$$\begin{aligned} r(t) &= \ln(1 + \eta(t)) \\ d\eta(t) &= \eta(t)(\alpha(t)dt + \sigma(t)dW(t)) \end{aligned} \tag{20}$$

The Dothan model, BKi model, and the exponential Vasicek model given below imply that r is lognormally distributed. While this finding may seem reasonable, it is the cause for the explosion of the bank account; that is, from a single unit of money, one may be able to make in an infinitesimal interval of time an infinite amount of money. The Sandmann-Sondermann model overcomes this problem by modeling the short rates as above.

The Chen model (Chen, 1995) is

$$\begin{aligned} dr(t) &= (\alpha(t) - r(t))dt + (\sigma(t)r(t))^{1/2} dW^1(t) \\ d\alpha(t) &= (\alpha - \alpha(t))dt + (\alpha(t))^{1/2} dW^2(t) \\ d\sigma(t) &= (\gamma - \sigma(t))dt + (\sigma(t))^{1/2} dW^3(t) \end{aligned} \tag{21}$$

where α, γ are constants and W^1, W^2 , and W^3 are independent Wiener processes. This is an example of a three-factor model.

The Schmidt model (Schmidt, 1997) is

$$r(t) = H[f(t) + g(t)W(T(t))] \tag{22}$$

where $T = T(t)$ and $H = H(x)$ are continuous nonnegative strictly increasing functions of $t \geq 0$ and real x , while $f = f(t)$ and $g = g(t) > 0$ are continuous functions.

The exponential Vasicek model is

$$dr(t) = r(t) [\eta - a \ln r(t)] dt + \sigma r(t) dW(t) \tag{23}$$

This model is similar to the Dothan model, being a lognormal short-rate model. This model does not lead to explicit formulae for pure discount bonds or for options contingent on them. In addition, this is an example of a nonaffine term-structure model.

The Mercurio-Moraleda model (Mercurio and Moraleda, 2000) is

$$\begin{aligned} dr(t) &= r(t) \left[\eta(t) - \left(\lambda - \frac{\gamma}{1 + \gamma t} \right) \ln r(t) \right] dt \\ &\quad + \sigma r(t) dW(t) \end{aligned} \tag{24}$$

The CIR++ model (Brigo and Mercurio, 2007) is

$$\begin{aligned} r(t) &= x(t) + \varphi(t) \\ dx(t) &= k[\theta - x(t)]dt + \sigma\sqrt{x(t)}dW(t) \end{aligned} \quad (25)$$

The extended exponential Vasicek model (Brigo and Mercurio, 2007) is

$$\begin{aligned} r(t) &= x(t) + \varphi(t) \\ dx(t) &= x(t)[\eta - \lambda \ln x(t)]dt + \sigma x(t)dW(t) \end{aligned} \quad (26)$$

Two-factor models were based on a second source of random shocks. Two-factor models were developed by Brennan and Schwartz (1982), Fong and Vasicek (1992), and Longstaff and Schwartz (1992a). However, Hogan (1993) proved that the solution to the Brennan and Schwartz model explodes, that is, reaches infinity in a finite amount of time with positive probability. This shows that adding more factors may cause unseen problems. More complex multifactor models are described by Rebonato (1998) and by Brigo and Mercurio (1997).

Therefore, the *short-rate models* lead to two main problems. Mean-reverting models such as Vasicek or Hull and White may produce negative interest rates. From a computational perspective, if the risk-neutral probability of producing such negative rates is negligible, then those scenarios can simply be ignored in a Monte Carlo setup. The so-called lognormal models ensure nonnegativity of interest rates but may become explosive due to the change of scale in the short-rate modeling. Multifactor short-rate models become rapidly computationally infeasible, and they may produce volatility surfaces that do not match those observed in the markets.

The problems signaled above for the short-rate models led to the development of new classes of models, more notably the LIBOR market models or BGM developed by Brace, Gatarek, and Musiela (1997); Jamshidian (1997); and Musiela and Rutkowski (1997). This model starts with a geometric Brownian motion for the forward LIBOR rate $L_i(t) := L(t; T_i, T_{i+1})$,

where $0 = T_0 < T_1 < \dots < T_n$ to acquire positivity of rates

$$dL_i(t) = \mu_i^Q(t)L_i(t)dt + \sigma_i(t)L_i(t)dW_i^Q(t) \quad (27)$$

where Q is the martingale measure corresponding to the numeraire $N(t) = p(t, T_n)$, also called the terminal measure because the numeraire is the price of the bond with the last tenor. Now $\prod_{k=i}^{n-1} (1 + (T_{k+1} - T_k)L_k(t)) = \frac{p(t, T_i)}{p(t, T_n)}$ is the numeraire rebased price of a traded asset, the zero-coupon bond with maturity T_i . Hence, it should be a martingale and its drift must be zero. Calculating the drift with Ito calculus for all consecutive indexes $i, i + 1$ allows the drift determination

$$\mu_i^Q(t) = \sum_{\substack{k \geq i+1 \\ k \leq n}} \frac{(T_{k+1} - T_k)L_k(t)}{[1 + (T_{k+1} - T_k)L_k(t)]} \sigma_i(t)\sigma_k(t)\rho_{i,k}(t) \quad (28)$$

for all $i \in \{0, \dots, n - 1\}$.

Other numeraires are also feasible but lead to a different style of *calibration*. The pricing of interest rate derivatives is realized with Monte Carlo simulation.

The quest for ensuring positiveness of the short rates motivated the development of a new class sometimes called Markov functional models. Important contributions in this area are Flesaker and Hughston (1996), Rogers (1997), and Rutkowski (1997), although some seminal ideas are also contained in Constantinides (1992). In a nutshell, given a strictly positive diffusion process $\{D(t)\}_{t \geq 0}$ adapted to the filtration of the probability space, the term-structure model described by $p(t, T) = \frac{E_t^P[D(T)]}{D(t)}$ is arbitrage free, and if the diffusion process is also a supermartingale, then the short-rate process $\{r(t)\}_{t \geq 0}$ is positive with probability P one.

MODELING IN PRACTICE

One popular way of turning theory into practice is to use a *tree* approach to modeling. The

Table 1 Market Spot and Forward Rates

Time (Months)	Implied Spot Zero Rates	Implied Forward Rates
6	5.0000%	5.0000%
12	5.1266%	5.2533%
18	5.2544%	5.5103%
24	5.3835%	5.7714%
30	5.5141%	6.0371%
36	5.6462%	6.3080%

tree can be either binomial or trinomial in its construction. To illustrate the idea, consider first the binomial approach. The tree could be set up to reflect observed or estimated market short rates, and the data provided in Table 1 will help to demonstrate this idea.

The process starts from the first six-month period where the rate is known to be 5.000%. At the end of the six-month period, the following six-month forward rates are treated as being the short rates and are split, allowing interest rates to rise with a probability of 0.5 or fall with a probability of 0.5, but also taking into account the short-rate volatility. For a description of how this is achieved, see Eales (2000). Figure 1 shows how the rates would appear in a binomial tree once the procedure has been performed.

When the rates have been established, they must then be calibrated. The calibration procedure is achieved using the observed market price of a bullet government bond and pricing the bond using the “tree” calculated rates to obtain the appropriate discount fac-

tors. Consider a three-year-to-maturity government bond trading at par and offering a coupon of 5.625% paid semiannually as an example. On maturity, the bond will be redeemed for 102.8125, which is made up of the bond’s face value, say 100, and one half of the annual coupon, 2.8125.

Figure 2 illustrates how, moving back through the tree, the discounting process of the terminal payment taken together with the discounted interim coupons generate a bond price of 100.013. Given that the observed bond price is 100, the rates in the tree will need to be adjusted to ensure that the backward calculated price agrees with the market price of the bond. In this example the adjustment factor is 0.6 basis points, and this will be added to every node in the tree with the exception of the starting value. The resulting rates will then be as displayed in Figure 3.

The calibrated tree can now be used to calculate corporate bond spreads as well as bond options. The outlined procedure is close to that advanced by Black, Derman, and Toy in that the process fits observed market rates and short-rate volatility. There is, however, a danger that interest rates could go negative in this procedure.

As an alternative to this binomial approach, Hull and White (1994) have suggested a two-stage methodology that uses a mean-reverting process with the short rate as the source of uncertainty and calculated in a trinomial tree framework. The first stage in the approach

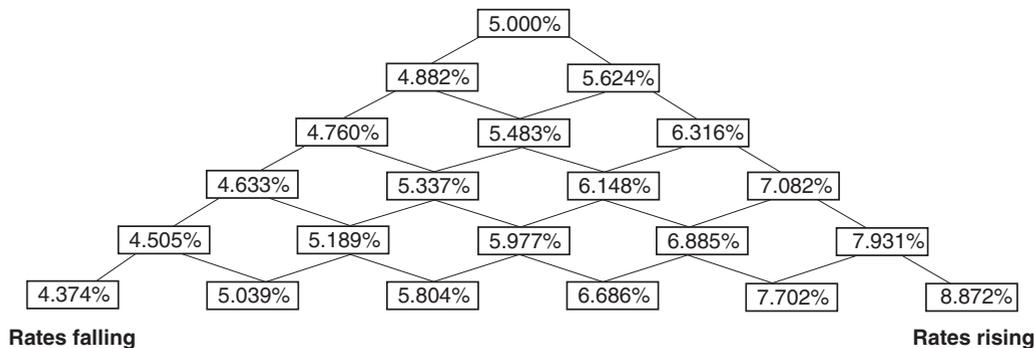

Figure 1 Term Structure Evolution: Binomial Tree

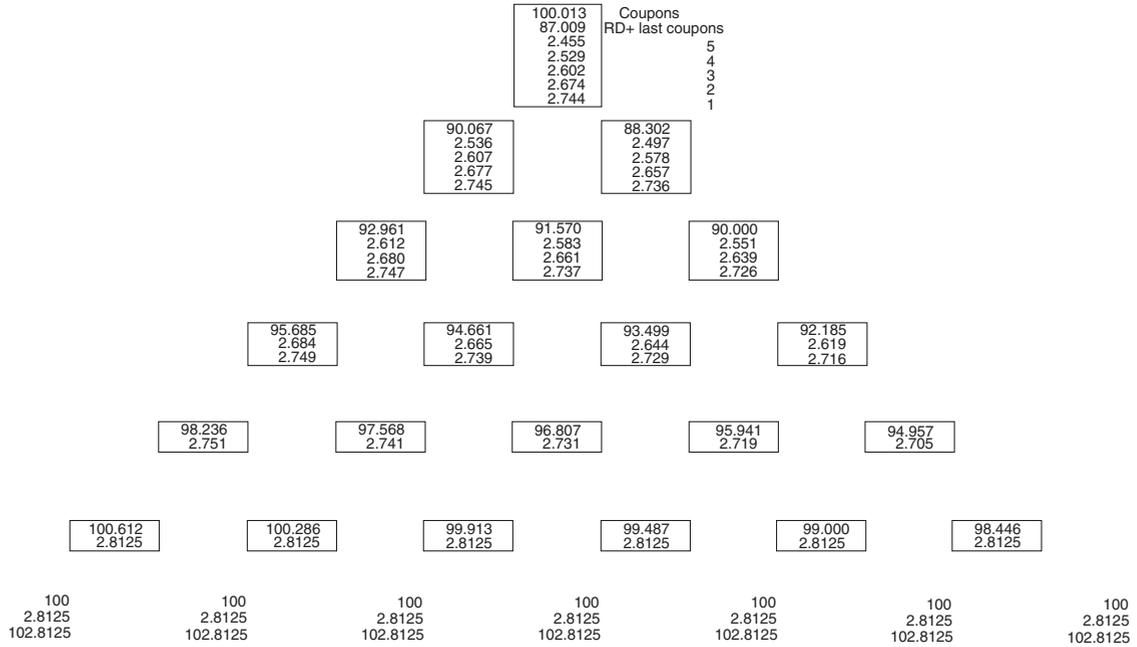

Figure 2 Calibration

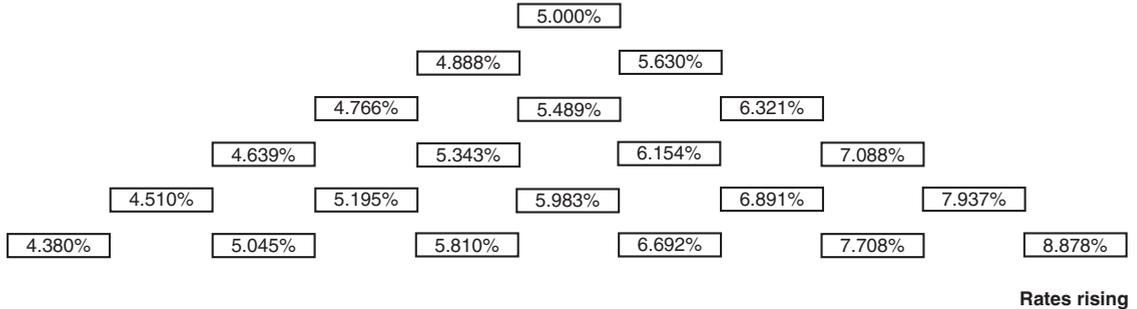

Figure 3 Adjusted Tree to Coincide with Current Market Price

ignores the observed market rates and centers the evolution of rates around zero and identifies the point at which the mean-reversion process takes effect. The second stage introduces the observed market rates into the framework established in stage one. The trinomial approach gives the tree a great deal more flexibility over its binomial counterpart, not least in relaxing the assumption that rates can either rise or fall with probability 0.5.

HJM METHODOLOGY

Heath, Jarrow, and Morton (1990a, 1990b, 1992) derived both one-factor and multifactor models for movements of the forward rates of interest. The models were complex enough to match the current observable term structure of forward rate and by equivalence the *spot rates*. Ritchken and Sankarasubramanian (1995) provide necessary and sufficient conditions for the HJM

models with one source of error and two state variables such that the *ex post* forward premium and the integrated variance factor are sufficient statistics for the construction of the entire term structure at any future point in time.

Under this methodology, the bond dynamics are described by an Ito process:

$$dp(t, T) = r(t)p(t, T)dt + \sigma(t, T)p(t, T)dW(t) \tag{29}$$

Then

$$d \ln p(t, T) = \left[r(t) - \frac{1}{2}\sigma^2(t, T) \right] dt + \sigma(t, T)dW(t) \tag{30}$$

The equation for the forward rate can be derived now:

$$\begin{aligned} df(t, T) &= -d \left(\frac{\partial}{\partial T} \ln p(t, T) \right) = - \left(\frac{\partial}{\partial T} d \ln p(t, T) \right) \\ &= - \frac{\partial}{\partial T} \left\{ \left[r(t) - \frac{1}{2}\sigma^2(t, T) \right] dt + \sigma(t, T)dW(t) \right\} \\ &= \sigma(t, T) \frac{\partial \sigma(t, T)}{\partial T} dt - \frac{\partial \sigma(t, T)}{\partial T} dW(t) \end{aligned} \tag{31}$$

The Wiener process $W = \{W(t)\}$ is symmetric, and therefore we can safely replace W with $-W$, so

$$df(t, T) = \sigma(t, T) \frac{\partial \sigma(t, T)}{\partial T} dt + \frac{\partial \sigma(t, T)}{\partial T} dW(t) \tag{32}$$

Applying the fundamental theorem of calculus for $\partial \sigma(t, T)/\partial T$ leads to

$$\sigma(t, T) - \sigma(t, t) = \int_t^T \frac{\partial \sigma(t, s)}{\partial s} ds \tag{33}$$

It is obvious that $\sigma(t, t) = 0$ and therefore the volatility of the forward rate determines the drift as well. In other words, all that is needed for the HJM methodology is the volatility of the bond prices. The short rates are easily calculated from the forward rates. Once a model for short rates is determined under the risk-neutral measure Q , the bond prices are calculated from

$$p(t, T) = E^Q \left[e^{-\int_t^T r(s)ds} | F_t \right] \tag{34}$$

Using (3) it follows that $\int_t^T f(t, s)ds = -\ln p(t, T) = g(r(t), t, T)$ where

$$g(x, t, T) = -\ln E^Q \left[e^{-\int_t^T r(s)ds} | r(t) = x \right] \tag{35}$$

The continuous variant of the Ho-Lee model can be obtained for

$$\begin{aligned} g(x, t, T) &= x(T-t) - \frac{1}{6}\sigma^2(T-t)^3 \\ &\quad + \int_t^T (T-s)\alpha(s)ds \end{aligned} \tag{36}$$

where $\sigma(t, T) = \sigma(T-t)$, which implies that $\frac{\partial f(t, T)}{\partial t} = \sigma^2(T-t)dt + \sigma dW(t)$ so the initial forward curve is

$$\begin{aligned} f(0, T) &= \frac{\partial g(r(0), 0, T)}{\partial T} = r(0) - \frac{1}{2}\sigma^2 T^2 \\ &\quad + \int_0^T \alpha(s)ds \end{aligned} \tag{37}$$

The short rate is given by

$$r(t) = f(0, t) + \sigma^2 \frac{t^2}{2} + \sigma W(t) \tag{38}$$

and the price of the pure discount bond with maturity T is

$$\begin{aligned} p(t, T) &= \exp \left[- \int_t^T f(t, s)ds - \sigma^2 t \right. \\ &\quad \left. \int_t^T \left(s - \frac{t}{2} \right) ds - \sigma(T-t)W(t) \right] \end{aligned} \tag{39}$$

Similarly, the Vasicek model is recovered for

$$\begin{aligned} \sigma(t, T) &= \sigma e^{-\beta(T-t)} \text{ and } f(0, T) \\ &= \frac{\alpha}{\beta} + e^{-\beta T} \left(r(0) - \frac{\alpha}{\beta} \right) - \frac{\sigma^2}{2\beta^2} (1 - e^{-\beta T})^2 \end{aligned} \tag{40}$$

and this leads to

$$r(t) = \frac{\alpha}{\beta} + e^{-\beta t} \left(r(0) - \frac{\alpha}{\beta} \right) + \sigma e^{-\beta t} \int_0^t e^{\beta s} dW(s) \tag{41}$$

BOND OPTION PRICING

Formulae for bond options were found by Cox, Ingersoll, and Ross using the CIR model (square root process) for short rates and by Jamshidian (1989), Rabinovitch (1989), and Chaplin (1987) using the Vasicek model for the short-rate process. Rabinovitch advocated the idea that the bond follows a lognormal process (similar to equity prices). Chen (1991) pointed out that this assumption is grossly misleading since the bond price is a contingent claim on the same interest rate, so the *bond option pricing* model cannot be a two-factor model as proposed by Rabinovitch and it rather collapses onto a one-factor model, in which case the formulas are the same with those proved respectively by Chaplin (1987) and by Jamshidian (1989).

Bonds are traded generally over the counter. Futures contracts on bonds may be more liquid and may remove some of the modeling difficulties generated by the known value at maturity of the bonds. Hedging may be more efficient in this context using the futures contracts on pure discount bonds (provided they are liquid) rather than the bonds themselves. Chen (1992) provides closed-form solutions for futures and European futures options on pure discount bonds, under the Vasicek model.

Hull and White used a two-factor version of the Vasicek model to price discount bond options. Turnbull and Milne (1991) proposed a general equilibrium model outside the *HJM framework*. They provide analytical solutions for European options on Treasury bills, interest rate forward and futures contracts, and Treasury bonds. In addition, a closed formula is identified for a call option written on an interest rate cap. A two-factor model is also investigated, and closed-form solutions are provided for a European call on a Treasury bill. Chen and Scott (1992) use a two-factor CIR model that is essentially the same as the model analyzed by Longstaff and Schwartz (1992), and derive solutions for bond and interest rate options. The two-factor model is used, with the first factor having a strong mean reversion, explaining the

variation in short-term rates, while the second factor has a very slow mean reversion, modeling long-term rates. The model is also used for calculating premiums for caps on floating interest rates and for European options on discount bonds, coupon bonds, coupon bond futures, and Eurodollar futures. These are not closed-form solutions, but they are expressed as multivariate integrals. However, the calculus can be reduced to univariate numerical integrations.

European Options on the Money Fund

In this section we consider the pricing of a European option on the money fund (this is the same as a bank account when the initial value $B(0)=1$). Thus, the payoff of a European call option with exercise price K is $\max[B(T) - K, 0]$. The continuous version of the Ho-Lee model is assumed for the short interest rate process. The risk-neutral valuation methodology provides the solution as

$$\begin{aligned} c_{B(0),T,K} &= E^Q \left[e^{-\int_0^T r(u)du} \max[B(T) - K, 0] \right] \\ &= B(0)N(d_+) - p(0, T)KN(d_-) \quad (42) \end{aligned}$$

where

$$\begin{aligned} d_+ &= \frac{\ln\left(\frac{B(0)}{p(0,T)K}\right) + \sigma^2 \frac{T^3}{6}}{\sigma \sqrt{\frac{T^3}{3}}} \quad \text{and} \\ d_- &= \frac{\ln\left(\frac{B(0)}{p(0,T)K}\right) - \sigma^2 \frac{T^3}{6}}{\sigma \sqrt{\frac{T^3}{3}}} = d_+ - \sigma \sqrt{\frac{T^3}{3}} \end{aligned}$$

A proof of this formula is described in Epps (2000) in Section 10.2.2.

Options on Discount Bonds

Discount bond options are not very liquid, but they form an elementary component for pricing other options. For example, a floating rate cap can be decomposed into a portfolio of European puts on discount bonds. Similarly, with the European option contingent to the bank account,

we can price European options contingent on discount bonds.

When the short rate process $r = \{r(t)\}$ follows the continuous time version of the Ho-Lee model given above by (10), the price at time 0 of a European call option with maturity T_0 with exercise price K on a discount bond maturing at T ($T_0 < T$) is

$$\begin{aligned}
 c_{p(0,T);T_0;K} &= E^Q \left[e^{-\int_0^T r(u)du} \max[p(T_0, T) - K, 0] \right] \\
 &= p(0, T_0) \frac{p(0, T)}{p(0, T_0)} N(d_+) \\
 &\quad - p(0, T_0) K N(d_-) \tag{43}
 \end{aligned}$$

where

$$\begin{aligned}
 d_+ &= \frac{\ln\left(\frac{p(0,T)}{p(0,T_0)K}\right) + \sigma^2 \frac{(T-T_0)T_0}{2}}{\sigma \sqrt{(T-T_0)T_0}} \quad \text{and} \\
 d_- &= d_+ - \sigma \sqrt{(T-T_0)T_0}
 \end{aligned}$$

A proof of this result is provided in Epps (2000). There is a similar put-call parity for European options contingent on a discount bond. If $p_{p(0,T);T_0;K}$ is the price at $t = 0$ of a European put option on the discount bond with maturity T , then for $B(0) = 1$,

$$\begin{aligned}
 c_{p(0,T);T_0;K} - p_{p(0,T);T_0;K} &= E^Q [e^{-\int_0^{T_0} r(s)ds} (\max[p(T_0, T) - K, 0] \\
 &\quad - \max[K - p(T_0, T), 0])] \\
 &= E^Q [e^{-\int_0^{T_0} r(s)ds} [p(T_0, T) - K]] \\
 &= E^Q [e^{-\int_0^T r(s)ds}] - p(0, T_0)K \\
 &= p(0, T) - p(0, T_0)K
 \end{aligned}$$

Put-call parity can be used to derive the price of a European put option:

$$\begin{aligned}
 p_{p(0,T);T_0;K} &= p(0, T_0) K N(-d_-) \\
 &\quad - p(0, T_0) \frac{p(0, T)}{p(0, T_0)} N(-d_+) \tag{44}
 \end{aligned}$$

Initially, the first formulas on pricing options on pure discount bonds used the Vasicek model for the term structure of interest rates. Thus, given that r follows (6), the price of a European

call option with maturity T_0 with exercise price K on a discount bond maturing at T ($T_0 < T$) is

$$c_{p(0,T);T_0;K} = p(0, T)N(d_+) - Kp(0, T_0)N(d_-) \tag{45}$$

where $d_+ = \frac{\ln\left(\frac{p(0,T)}{Kp(0,T_0)}\right) + \eta^2/2}{\eta}$ and $d_- = d_+ - \eta$, with $\eta = \frac{\sigma(1-e^{-\beta(T-T_0)})}{\beta} \sqrt{\frac{1-e^{-2\beta T_0}}{2\beta}}$

The put price can be obtained from put-call parity as

$$p_{p(0,T);T_0;K} = Kp(0, T_0)N(-d_-) - p(0, T)N(d_+) \tag{46}$$

Example: Valuing a Zero-Coupon Bond Call Option with the Vasicek Model

Let's consider this model for pricing a 3-year European call option on a 10-year zero-coupon bond with face value \$1 and exercise price K equal to \$0.5. As in Jackson and Staunton (2001), we use for the parameters of this model the values estimated by Chan et al. (1992) for U.S. 1-month Treasury bill yield from 1964 to 1989. Thus, $\alpha = 0.0154$, $\beta = 0.1779$, and $\sigma = 2\%$. In addition, the value of the short rate r at time $t = 0$ is needed, so we take $r_0 = 3.75\%$. Feeding this information into the above formulas, we get the output in Table 2. Thus, the value of the European call option is

$$\begin{aligned}
 c_{p(0,T);T_0;K} &= 0.5406 \times 0.9822 - 0.5 \times 0.8655 \\
 &\quad \times 0.9767 \cong 0.108
 \end{aligned}$$

A more general case is discussed by Shiryaev (1999) for single-factor Gaussian models modeling the short interest rate. These are single-factor affine models where the short rate r is also a Gauss-Markov process. The equation for this short rate process is

$$dr(t) = [\alpha(t) - \beta(t)r(t)]dt + \sigma(t)dW(t) \tag{47}$$

Table 2 Calculations of Elements for Pricing a European Call Option on a Zero-Coupon Bond When Short Rates Are Following the Vasicek Model

$p(0,T_0)$	$p(0,T)$	d_+	d_-	$N(d_+)$	$N(d_-)$
0.8655	0.5406	2.1013	1.9926	0.9822	0.9767

and we can easily recognize the first *Hull-White model*. The price of a European call option is also

$$c_{p(0,T);T_0;K} = p(0, T)N(d_+) - Kp(0, T_0)N(d_-) \quad (48)$$

but where

$$d_+ = \frac{\ln\left(\frac{p(0,T)}{Kp(0,T_0)}\right) + \frac{1}{2}\eta^2(T_0, T)B^2(T_0, T)}{\eta(T_0, T)B(T_0, T)} \quad \text{and}$$

$$d_- = d_+ - \eta$$

with

$$B(T_0, T) = \int_{T_0}^T \frac{\varphi(s)}{\varphi(T_0)} ds \quad \text{and} \quad \varphi(s) = e^{-\int_0^s \beta(u) du}$$

The price of the European put option is obviously again $p_{p(0,T);T_0;K} = Kp(0, T_0)N(-d_-) - p(0, T)N(d_+)$.

Example: Valuing a Zero-Coupon Bond Call Option with the Hull-White Model

When considering the pricing of a forward pure discount bond earlier in this entry, we used a numerical example. That example can now be expanded to demonstrate how, in practice, European calls and puts can be estimated in a Hull-White framework. Explicitly, the illustration will demonstrate the pricing of a one-year European call option on a four-year-to-maturity discount bond with a strike price set equal to the forward price of the bond (0.8858...).

Breaking down (d_+) into its component parts and evaluating each individually yields:

$$\begin{aligned} \ln\left(\frac{p(0, T)}{K(p(0, T_0))}\right) &= \ln\left(\frac{0.8521}{(0.8858)(0.9607)}\right) \\ &= 0, \quad B(T_0, T) = 2.5918 \\ \eta &= \frac{\sigma(1 - e^{-\beta(T-T_0)})}{\beta} \sqrt{\frac{1 - e^{-2\beta T_0}}{2\beta}} \\ &= \frac{0.02(1 - e^{-0.1(3)})}{0.1} \sqrt{\frac{1 - e^{-2(0.1)(1)}}{2(0.1)}} = 0.0493 \end{aligned}$$

The expression for (d_+) reduces to

$$\frac{\eta(T_0, T)B(T_0, T)}{2} = \frac{(0.0493)(2.5918)}{2} = 0.6395$$

The expression for d_- is (d_-) = (d_+) - η = 0.6395 - 0.0493 = 0.0146. $N(d_+)$ is found to be 0.5255 and $N(d_-)$ = 0.5058. Substituting these

results into the call option formula gives a premium of

$$\begin{aligned} c_{p(0,T);T_0;K} &= (0.8521)(0.5255) \\ &\quad - (0.8858)(0.9608)(0.5058) \\ &= 0.01730 \end{aligned}$$

or 1.73%.

One notable exception from this general class is the CIR model. There is a closed formula for this case, too. Following Clewlow and Strickland (1998), the price at time 0 of a European pure discount bond option is

$$\begin{aligned} c_{p(0,T);T_0;K} &= p(0, T)\chi^2\left(2\delta[\phi + \psi + B(T_0, T)]; 2\omega, \right. \\ &\quad \left. \frac{2\phi^2 r(0)e^{\theta T_0}}{\phi + \psi + B(T_0, T)}\right) \\ &\quad - Kp(0, T_0)\chi^2\left(2\delta[\phi + \psi]; 2\omega, \frac{2\phi^2 r(0)e^{\theta T_0}}{\phi + \psi}\right) \end{aligned} \quad (49)$$

where

$$\begin{aligned} \theta &= \sqrt{\beta^2 + 2\sigma^2}, \quad \phi = \frac{2\theta}{\sigma^2(e^{-\theta T} - 1)}, \\ \psi &= \frac{\beta + \theta}{\sigma^2}, \quad \lambda = \frac{\beta + \theta}{2}, \quad \omega = \frac{2\beta}{\sigma^2}, \\ B(t, s) &= \left(\frac{e^{\theta(s-t)} - 1}{\lambda(e^{\theta(s-t)} - 1) + \theta}\right), \\ \delta &= \frac{\omega(\lambda T + \ln \theta - \ln[\lambda(e^{\theta T} - 1) + \theta]) - \ln(K)}{B(T_0, T)} \end{aligned}$$

and $\chi^2(.; a, b)$ is the noncentral chi-squared density with a degrees of freedom and noncentral parameter b .

Example: Valuing a Zero-Coupon Bond Call Option with the CIR Model

Let's consider the same problem as described in the example using the Vasicek model above and price the 3-year European call option on a 10-year pure discount bond using the CIR model for the short interest rates. Recall that face value is \$1 and exercise price K is equal to \$0.5. As in the example with the Vasicek model, we consider that $\sigma = 2\%$ and $r_0 = 3.75\%$. The CIR model overcomes the problem of negative

interest rates known for the Vasicek model as long as $2\alpha \geq \sigma^2$. This is true, for example, if we take $\alpha = 0.0189$ and $\beta = 0.24$. Feeding this information into the above formulas is relatively tedious. A spreadsheet application is provided by Jackson and Staunton. After some work, we get that the price of the call is

$$c_{p(0,T);T_0;K} = 0.5324 \times 1 - 0.5 \times 0.8624 \times 1 \cong 0.1012$$

Options on Coupon-Paying Bonds

When short rates are modeled with single-factor models, Jamshidian (1989) proved that an option on a coupon bond can be priced by valuing a portfolio of options on discount bonds. This approach does not work in multifactor models as proved by El Karoui and Rochet (1995).

Consider a bond paying a periodic cash payment ρ at times T_1, T_2, \dots, T_m , and the principal at maturity $T = T_m$. A coupon bond can be mapped into a portfolio of discount bonds with corresponding maturities (under one source of uncertainty, that is, one factor model). The value of a coupon-bearing bond at time $t < T_m$ is

$$p(t, T_1, \dots, T_m; \rho) = \rho \sum_{i=i[t]}^m p(t, T_i) + p(t, T_m) \tag{50}$$

where $i[t] = \min\{j : t < T_j\}$.

Under the one-factor HJM model corresponding to the Ho-Lee model, a European option on a coupon bond can be valued as a portfolio of options contingent on zero discount bonds with maturities T_1, T_2, \dots, T_m . Let T_0 be the maturity of such a European option.

Epps (2000) shows that

$$p(T_0, T_i) = \frac{p(0, T_i)}{p(0, T_0)} e^{\left[-\sigma^2 \frac{(T_i - T_0)^2 T_0}{2} - (T_i - T_0)(r(T_0) - f(0, T_0)) \right]} \tag{51}$$

For any strike price K , there is a value r_K of $r(T_0)$ such that when replaced in (48) with $t = T_0$, implies $p(T_0, T_1, \dots, T_m) = K$. Let's de-

note by K_i the value of $p(T_0, T_i)$ as calculated from (49) with r_K instead of $r(T_0)$. Then

$$\rho \sum_{i=i[T_0]}^m K_i + K_m = K \tag{52}$$

Hence, the value at time 0 of a European call option with maturity T_0 and strike price K on the coupon-bearing bond, under the one-factor HJM model described above, is given by

$$\begin{aligned} c_{p(0,T_1,\dots,T_m;\rho)} &= E^Q \left\{ e^{-\int_0^{T_0} r(s)ds} \max[p(T_0, T_1, \dots, T_m; \rho) - K, 0] \right\} \\ &= \rho \sum_{i=i[T_0]}^K E^Q \left\{ e^{-\int_0^{T_0} r(s)ds} \max[p(T_0, T_i) - K_i, 0] \right\} \\ &\quad + E^Q \left\{ e^{-\int_0^{T_0} r(s)ds} \max[p(T_0, T_m) - K_m, 0] \right\} \\ &= \rho \sum_{i=i[T_0]}^m c_{p(0,T_i);T_0,K_i} + c_{p(0,T_m);T_0;K_m} \end{aligned} \tag{53}$$

Example: Valuing a Coupon-Bond Call Option with the Vasicek Model

The above example is reconsidered using the Vasicek model for the short-term interest rates. The bond is no longer a zero-bond but now pays an annual coupon at a 5% rate ($\rho = 0.05$), all the other characteristics being the same as before. In order to calculate the European call option price on the coupon bond, we need to calculate the interest rate r_K such that the present value at the maturity of the option of all later cash flows on the bond equals the strike price. This is done by trial and error using (48), and the value we get here is $r_K = 22.30\%$. Next, we map the strike price into a series of strike prices via (50) that are then associated with coupon payments considered as zero-coupon bonds and calculate the value of the European call options contingent on those zero-coupon bonds as in the preceding example. The calculations are described in Table 3.

Because we started with a one-factor model for the short interest rates, we can use the decomposition property emphasized by Jamshidian (1997) and calculate the required coupon-bond European call price as the sum

Table 3 Calculations Using the Vasicek Model for Separate Zero-Coupon European Call Options (bond prices shown are calculated with the estimated r_K)

Year	$p(T_0, T_i) r_K$	Face Value	ρK_i	Call Option
4.0	0.8094	0.05	0.0405	0.006
5.0	0.6688	0.05	0.0334	0.009
6.0	0.5624	0.05	0.0281	0.012
7.0	0.4800	0.05	0.0240	0.013
8.0	0.4148	0.05	0.0207	0.013
9.0	0.3622	0.05	0.0181	0.013
10.0	0.3192	1.05	0.3351	0.278

of all the elements in the last column in Table 3, which includes the coupon rate factor ρ . Thus, the value of this option is 0.344.

Example: Valuing a Coupon-Bond Call Option with the CIR Model

We repeat the calculation of the coupon-bond call option when the CIR model is employed for the short rates. The procedure is the same as in the case discussed previously for the Vasicek model. First, we calculate the interest rate r_K such that the present value at the maturity of the option of all later cash flows on the bond equals the strike price. This value is here $r_K = 25.05\%$. Next, we map the strike price into a series of strike prices via (50) that are then associated with coupon payments considered as zero-coupon bonds and calculate the value of the European call options contingent to those zero-coupon bonds. The calculations are described in Table 4.

Table 4 Calculations Using the CIR Model for Separate Zero-Coupon European Call Options (bond prices shown are calculated with the estimated r_K)

Year	$p(T_0, T_i) r_K$	Face Value	ρK_i	Call Option
4.0	0.7934	0.05	0.0397	0.006
5.0	0.6503	0.05	0.0325	0.010
6.0	0.5470	0.05	0.0273	0.012
7.0	0.4694	0.05	0.0235	0.013
8.0	0.4094	0.05	0.0205	0.013
9.0	0.3615	0.05	0.0181	0.013
10.0	0.3223	1.05	0.3385	0.267

The value of the call option is 0.334, that is, the sum of all zero-coupon bond call option prices in the last column.

Pricing Swaptions

Swaptions options allow the buyer to obtain at a future time one position in a swap contract. It is elementary that an interest rate swap, fixed for floating, can be understood as a portfolio of bonds. Let's consider here that the notional principal is 1. Then the claim on the fixed payments is the same as a bond paying coupons with the rate ρ and no principal. Let τ be the time when the swap is conceived. The claim on the fixed income stream is worth, at time τ , $\rho \sum_{i=1}^m p(\tau, T_i)$. The floating income stream is made up of cash returns on holding, over the period $[T_{i-1}, T_i]$ a discount bond with maturity T_i , which is worth $\frac{p(T_i, T_i)}{p(T_{i-1}, T_i)} - 1$. Thus, the value of the whole floating stream at time $t = \tau$ is

$$\begin{aligned} E_\tau \left(\sum_{i=1}^m e^{-\int_\tau^{T_i} r(s)ds} \frac{1 - p(T_{i-1}, T_i)}{p(T_{i-1}, T_i)} \right) \\ = E_\tau \left(\sum_{i=1}^m e^{-\int_\tau^{T_{i-1}} r(s)ds} e^{-\int_{T_{i-1}}^{T_i} r(s)ds} \frac{1 - p(T_{i-1}, T_i)}{p(T_{i-1}, T_i)} \right) \end{aligned} \quad (54)$$

Applying the properties of conditional expectations it follows that the above is equal to

$$\begin{aligned} E_\tau \left\{ \sum_{i=1}^m e^{-\int_\tau^{T_{i-1}} r(s)ds} \left(E_{T_{i-1}} e^{-\int_{T_{i-1}}^{T_i} r(s)ds} \left[\frac{1 - p(T_{i-1}, T_i)}{p(T_{i-1}, T_i)} \right] \right) \right\} \\ = E_\tau \left\{ \sum_{i=1}^m e^{-\int_\tau^{T_{i-1}} r(s)ds} (1 - p(T_{i-1}, T_i)) \right\} \\ = \sum_{i=1}^m [p(\tau, T_{i-1}) - p(\tau, T_i)] = 1 - p(\tau, T_m) \end{aligned} \quad (55)$$

Imposing the condition that the two streams have equal initial value leads to

$$\rho \sum_{i=1}^m p(\tau, T_i) = 1 - p(\tau, T_m)$$

which is equivalent to

$$\rho \sum_{i=1}^m p(\tau, T_i) + p(\tau, T_m) - 1 = 0$$

It follows then that the value of the swap at initialization is $p(\tau, T_1, \dots, T_m) - 1$. Thus, the option to get a long position in the fixed leg of the swap, with a fixed payment rate ρ , is worth at time 0

$$E_0^Q \left\{ e^{-\int_0^\tau r(s)ds} \max [p(\tau, T_1, \dots, T_m) - 1, 0] \right\} \quad (56)$$

It is clear now that this is the same as a European call option on a coupon-bearing bond when the exercise price is equal to 1.

PRACTICAL CONSIDERATIONS

As mentioned in the introduction, the 10-year U.S. Treasury note option traded on the CME is an extremely popular contract offering tight bid/ask spreads and transparent price quotes.

The Eurodollar futures option traded on the CME is the most actively traded short-term interest rate option in the world. If the option contracts are exercised, the buyer and the seller of the option take positions in the Eurodollar futures contract, which is cash-settled, and the final price at delivery is equal to 100 minus the three-month US dollar LIBOR.

Another liquid interest rate derivative market is the OTC in floating rate caps. The majority of caps are contingent on LIBOR (but can be also on a Treasury rate), and discounted payments are made at the beginning of each tenor. The payments can be made either at the beginning or the end of each reset period, and the life of a cap may be only a few years or as long as 10 years. The starting point in pricing these European options is a model for future changes in US dollar LIBOR.

Hull and White (1990) showed that the cap can be priced as a portfolio of European puts on discount bonds.

KEY POINTS

- One-factor short-rate models for interest rate derivatives are easy to work with since the majority of them lead to closed-form solutions for options pricing. However, some of them allow for negative interest rates, which may not be acceptable in a real trading environment.
- Two-factor models for interest rates provide improved calibration at the expense of computational simplicity.
- The two-factor Hull and White model, falling under the general Heath-Jarrow-Morton framework, is complex enough to calibrate market data easily while retaining computational simplicity through closed-form solutions for a wide range of interest rate derivatives.
- The need for improved calibration of forward curves led to the development of a different class of models called LIBOR models.
- The calibration of caps and floors, and also swaptions, is indicative of the success of an interest rate model.

Basics of Currency Option Pricing Models

SHANI SHAMAH

Senior Consultant, RBC Capital Markets

Abstract: Historically, theorists have devoted a substantial amount of work developing a mathematical model for pricing options and, hence, a number of different models exist as a result. All make certain assumptions about market behavior, which are not totally accurate, but which give the best solution to the price of an option. Professionals use these models to price their own options and to give theoretical fair value; however, actual market rates will always be the overriding determinant. In other words, an option is worth as much as someone is prepared to pay for it. Although the formula for pricing options is complex, they are all based on the same principles.

Historically, option-pricing models have fallen into two categories:

- Ad hoc models, which generally rely only upon empirical observation or curve fitting and, therefore, need not reflect any of the price restrictions imposed by economic equilibrium.
- Equilibrium models, which deduce option prices as the result of maximizing behavior on the part of market participants.

The acknowledged basis of modern option pricing formulas is the often-quoted Black-Scholes formula, devised by Black and Scholes (1973) to produce a “fair value” for options on equities. Of course, currency options differ because there is no dividend and both elements of the exchange carry *interest rates* that can be fixed until maturity. Therefore, various adaptations to the original Black-Scholes formula have been made for use in currency option pricing. The

best known of these is the Garman-Kohlhagen adaptation, which adequately allows for the two interest rates and the fact that a currency can trade at a premium or at a discount forward depending on the interest rate differential.

American-style options cause further problems in the pricing due to the probability of early exercise. Cox, Ross, and Rubinstein (1979) introduced a pricing model to take account of American-style options. By using the same basics as Black-Scholes, they adopted what is now known as the “binomial” method for pricing such options. This same binomial model is now used alongside the Garman-Kohlhagen version to price currency options.

BASIC PROPERTIES

First, though, there are a few basic properties of options, especially when looking at option prices to consider:

- Options cannot have a negative value to their holders. Since options are rights and these rights will be exercised to benefit only the holder, the option cannot be a liability to its holder.
- Option prices should not allow simple arbitrage; that is, it should not be possible to buy an American call or put and immediately exercise the option for a profit greater than the price paid for the option. This need not be true for European options, since the option holder does not have the right to exercise until the maturity date.
- American-type options should be worth at least as much as European-type options. Since *American* options have all the rights a *European* option has plus the right of early exercise, an American option will be as valuable as a European option if the right to early exercise is worthless and more valuable than a European option if the right of early exercise is valuable.

In addition to the currency price, the exercise price, and the time to maturity, option values depend on the price volatility of the underlying currency, the risk-free rate of interest, and any cash distributions made by the currency during the life of the option. For a call option, a higher current currency price should imply a greater value to the option holder. This is because a higher present currency price makes it more likely that on the expiration date, the market price of the currency will be above the exercise price. As this is precisely the condition under which the option will be exercised, the value of a call option increases as the present currency price increases. For put options, however, the effects of changes in the current asset price go in the opposite direction, as it pays the holder of the put to exercise when the currency price is low; that is, the value of a put option decreases as the present currency price increases.

The effect of the exercise price, X , on the value of the call option is straightforward. Holding all

other factors constant, a higher exercise price diminishes the profit from the exercise of the option. An increase in the exercise price would, therefore, lead to a decrease in the price of the call option. In the case of put options, a higher exercise price increases the profit from exercise of the option. Thus, put option prices increase with an increase in their exercise price.

The effect of an increase in time to maturity on the value of an option depends on the nature and type of option. There is an asymmetric nature to option contracts that causes the holder to benefit from increased uncertainty. The option holder stands to gain by a rise in uncertainty, and therefore the value of the call option increases as its time to maturity increases. Also, the present value of the exercise price decreases as the time to maturity increases. Therefore, the time left to maturity has a way of influencing option values. An American put option cannot logically decrease in value with an increased time to maturity, but with a European put option, the net effect of these two influences is ambiguous; that is, increased uncertainty increases value, while the decreased present value of the exercise price decreases value.

An increase in the volatility of the currency price makes future currency prices more variable and increases the probability of large gains. Again, the asymmetry of the option contract allows the option holder to benefit from increased uncertainty since the option is effectively insured against downside risk.

THEORETICAL VALUATION

The price and subsequent value of an option are determined by a theoretical valuation based on several known and estimated factors. The time until maturity, the current foreign exchange spot and forward exchange prices, the strike, and the cost of funding the *option premium* are all readily available. Meanwhile, a market has developed that estimates the future volatility

or, in other terms, the activity of the underlying cash product. The greater the anticipated movement, the greater the value of the option for a given fixed set of parameters. Options also increase in value the smaller the distance between the *strike price* and the forward foreign exchange rate, and the greater the time to maturity. For European and American options, most market participants accept the valuation put forward by Black and Scholes, and, as such, option prices can be agreed once the factors are entered into the equation.

This theoretical model also calculates the risk associated with changes in any of the variables required for pricing the currency option. The *delta*, or hedge ratio, of the option is the degree to which the option value will change with a movement in the underlying currency. A dollar/Swiss franc option with a 20% delta would change in value by approximately 20 franc points for every 100-point spot move. While the delta is the first derivative of the price, *gamma* is the second one, or change in delta for every move in the spot foreign exchange rate. A 50-delta dollar call option with a 15% gamma would have a 65 delta if the dollar appreciated 1%.

It is this dynamic nature of the delta that allows an option to be a leveraged product with limited risk and unlimited profit potential. Profitable positions effectively grow in size, while unprofitable trades are impacted less by adverse changes in the market.

The *vega*, or volatility risk, of an option is the extent to which the valuation will change with varying estimates of volatility. The *theta*, or time decay, is the decrease in value of the option as it approaches maturity, as an option is a constantly diminishing asset. Finally, every option has forward foreign exchange risk equivalent to the delta and an interest rate exposure based on changes in funding costs. The delta and interest rate risks can be hedged easily in the relevant markets. The dynamic nature of the other risks is the essence of the options market.

BLACK-SCHOLES MODEL

In 1973, Black and Scholes published a paper describing an equilibrium model of stock option pricing that is based on arbitrage. This is made possible by their crucial insight that it is possible to replicate the payoff to options by following a prescribed investment strategy involving the underlying asset and lending/borrowing.

The mathematics employed in the *Black-Scholes model* is complex, but the principle is straightforward. The model states that the stock and the call option on the stock are two comparable investments. Therefore, it should be possible to create a riskless portfolio by buying the stock and hedging it by selling call options. The hedge is a dynamic one because the stock and the option will not necessarily move by the same amount, but by continuously adjusting the option hedge to compensate for movement in the underlying market, the overall position should be riskless. Therefore, the income received from investing in the call option premium will be offset exactly by the cost of replicating (hedging) the position. If the option premium is too high, the arbitrageur will make a riskless profit by writing call options and hedging the underlying stock. If too low, it should be possible to profit by buying the call option and selling sufficient stock.

Black and Scholes demonstrated that the option premium could be arrived at through an arbitrage process in a similar manner to that in which a currency forward rate can be derived through a formula linking the spot rate and the interest rate differential. Also, in the same way that a currency *forward rate* is not “what the market thinks the currency will be worth at a future date” but simply based on an arbitrage relationship, the Black-Scholes model is not influenced by such factors as market sentiment, direction, or apparent bias. In fact, an assumption of the model is that the market moves in a random fashion in that, while prices will change, the chances of an up move against a down move are

about even, and that future price movements cannot be predicted from the behavior of the past.

The Model:

$$C = SN(d_1) - Ke^{(-rt)}N(d_2)$$

C = theoretical call premium

S = current stock price

t = time until option expiration

K = option striking price

r = risk-free interest rate

N = cumulative standard normal distribution

e = exponential term (2.7183)

$$d_1 = \frac{\ln(S/K) + \left(r + \frac{s^2}{2}\right)t}{s\sqrt{t}}$$

$$d_2 = d_1 - s\sqrt{t}$$

s = standard deviation of stock returns

ln = natural logarithm

Plotted over a period of time, the distribution of prices takes on the characteristics of the “bell-shaped” curve. Such a distribution is a key assumption of the Black-Scholes model, yet with the foreign exchange markets in particular, it is a questionable one. Even with its economic liquidity and its global 24-hour structure, foreign exchange is by no means a perfect market. Frequently, there are times when prices do not behave in a normally distributed fashion. Such occurrences as wars, central bank intervention, and unexpected political or economic news are all factors, which can and do disrupt the day-to-day business of the market.

Furthermore, in order to simplify the calculation process, Black and Scholes made other assumptions about market behavior, which may vary from the real world. They assumed that volatility was known and constant, that interest rates were constant, that there were no transaction costs or taxation effects, that trading was continuous, that there were no dividends payable, and that options could only be exercised on the expiry date.

Interest rates will vary, of course, as will volatility, and even the foreign exchange markets have transaction cost in the bid-offer spread. Frequently, the market will become very thin or almost untradable during highly volatile periods. However, most of these assumptions can be relaxed without inordinately affecting the formulations of the pricing model, and where the assumptions are more critical, other models have been developed.

EXAMPLES OF OTHER MODELS

Theorists have devoted a substantial amount of time and effort developing mathematical models for pricing options, and a number of different models exist as a result. All make certain assumptions about market behavior, which are not totally accurate, but which give the best solutions to the price of an option. For example, the model formulated by *Merton* (1973) generalized the Black-Scholes formula, so it could price European options on stocks or stock indexes paying a known dividend yield.

Another example is the *Cox, Ross, and Rubinstein model* (1979), which could account for the early exercise provisions in American-style options. Using the same parameters as in the Black-Scholes model, they adopted what is known as a “binomial” method to evaluate the premium. Making the assumption that the option market behaves efficiently and therefore the holder of a call or put option will exercise if the benefit of holding the option is outweighed by the cost of carrying the hedge, the binomial process involves taking a series of trial estimates over the life of the option; each estimate (or iteration) is a probability analysis of the likelihood of early exercise on any given day.

Garman and Kohlhagen (1983) extended the Black-Scholes model to cover the foreign exchange market, where they allowed for the fact that currency pricing involves two interest rates, not one, and that a currency can trade

at a premium or discount forward, depending on the interest rate differential. Like the Merton formula, the *Garman and Kohlhagen* formula applies only to European options.

PRICING WITHOUT A COMPUTER MODEL

Against all the above theories, there is a way to price an option without a computer model. This can be obtained by the following equation, which will give a good approximation for a European option premium. The formula is:

$$\text{Price} = \text{BB} \times \text{forward outright rate}$$

This is where:

$$\text{AA} = \text{square root} (\text{days to expiry}/365) \\ \times \text{volatility} \times 0.19947$$

and

$$\text{BB} = ((\text{AA} + 0.5) \times 2) - 1$$

This formula is where price is the premium for an at-the-money European option quoted in units per base currency.

Educated Guess

Another calculation relies heavily on probability theory. The principal concepts are expected value and the lognormal distribution. Since the future is unknown, it is an “educated guess” about where the spot market might be in order to determine the value of that right today. Thus, rather than trying to predict the future spot rate, option pricing takes a systematic, mathematical approach to the educated guess.

In this case, expected value (EV) is the payoff of an event multiplied by the probability of it occurring. For example, the probability of rolling a six on one die is 1/6 or 16.67%. The EV of a game in which is paid \$100 for rolling a six and nothing for any other roll is:

$$(1/6 \times \$100) + (5/6 \times \$0) = \$16.67$$

where the expected value is the fair price for playing such a game.

An options premium can be thought of in the same way, although instead of six possible outcomes, there are hundreds. All the spot rates that might prevail are the options expirations. Each outcome will have a specific value. This will either be zero if the option is out-of-the-money or the difference between the closing spot and the strike price if the option is in-the-money. Each closing spot rate can also be thought of as having its own discrete probability. If, for each outcome, the value of that outcome is multiplied by its probability and then the results are added up, the sum would be the premium of the option. The expected value of an option (the probability minus the weighted sum of all its possible payoffs) is the fair price for buying the option.

THE PRICE OF AN OPTION

The price of an option is made up of two separate components:

$$\text{Option premium} = \text{Intrinsic value} + \text{Time value}$$

where *intrinsic value* is the value of an option relative to the outright forward market price, that is, it represents the difference between the strike price of the option and the forward rate at which one could transact today. Intrinsic value can be zero but never negative.

There are six factors that contribute to this pricing of an option:

- Prevailing spot price
- Interest rate differentials (forward rate)
- Strike price
- Time to expiry
- Volatility
- Intrinsic value

As described above, the best-known original closed-form solution to option pricing is the Black-Scholes model. Also, as was mentioned, in its simplest form, it offers a solution to

pricing European-style options on assets with interim cash payouts over the life of the option. The model calculates the theoretical, or fair value for the option by constructing an instantaneously riskless hedge that is one whose performance is the mirror image of the option payout. The portfolio of option and hedge can then be assumed to earn the risk-free rate of return.

Central to the model is the assumption that markets' returns are normally distributed (that is, have lognormal prices), that there are no transaction costs, that volatility and interest rates remain constant throughout the life of the option, and that the market follows a diffusion process. The model has these five major inputs:

- The risk-free interest rate
- The option's strike price
- The price of the underlying
- The option's maturity
- The volatility assumed

Since the first four are usually determined, markets tend to trade the implied volatility of the option. For example, a six-month European-style sterling put/dollar call with the spot rate at $\$/\text{£}1.7500$ and forward points of 515, giving an outright forward of 1.6985 ($1.7500 - 0.0515$), will have an intrinsic value of 4.15 cents per pound.

While the Black-Scholes pricing formula looks formidable, it is important to understand that the formula is nothing more than the simple two-state option-pricing model applied with an instantaneous trading interval.

If the strike price of the option is more favorable than the current forward price, the option is said to be in-the-money. If the strike price is equal to the forward rate, it is an at-the-money option, and if the strike price is less favorable than the outright, the option is termed out-of-the-money.

For American-style options, a similar definition applies except that the option's "money-ness" relative to the spot price also needs to be

considered. Clearly, in the example above, an American-style option would be in-the-money relative to the forward but not to the spot. Conversely, if the option had the same details except that it was a call on sterling, it would clearly be out-of-the-money under the European definition, but as an American style option it would be in-the-money relative to the spot price. Naturally, the cost of the option would need to be considered in order to achieve a profitable early exercise of an American option and this leads to a phenomenon peculiar to American-style options known as "optimal exercise." This is the point at which it becomes profitable to exercise an American-style option early, having taken account of the premium paid.

Option Premium Profile

Figure 1 shows premium against spot at a given point in time. It can be seen that the time value call position is greatest when the option is at-the-money. This is because it represents the highest level of asymmetric risk, which is optimum risk reward profile.

The time value tends to zero as spot goes deep out-of-the-money and thus converges with the maximum loss expiry line and also as it goes deep in-the-money, converging with the unlimited profit expiry line. The change in the premium is not parallel to the change in the underlying value. The premium will change more rapidly when the option is near at-the-money and less rapidly when the option is in-the-money or out-of-the-money.

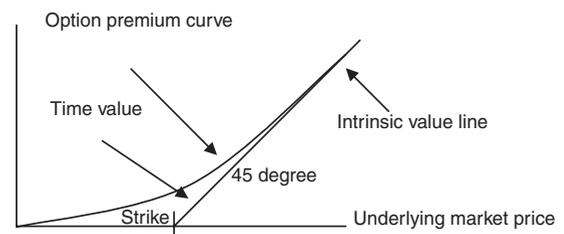

Figure 1 Option Premium Profile

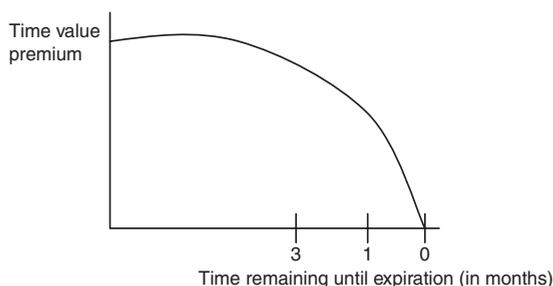

Figure 2 Time Value Premium Delay

Time Value and Intrinsic Value

The option premium can be split into two parts: intrinsic value and time value. The effect of an increase in time on an options premium is not linear. This is because the probability of a rise or fall in a currency's value does not increase on a straight-line basis. For example, all things being equal, the premium for an at-the-money three-month option is worth only about two-thirds more than for a one-month option (not three times its value). A one-year option is worth only about one-third more than a six-month option (instead of twice its value). As a consequence, the premium for at-the-money options declines at an accelerating rate towards expiry. Figure 2 demonstrates the time value premium delay.

Time value is affected by a number of factors:

- The time remaining to expiration.
- The volatility of the underlying spot market.
- The strike price of the option.
- The forward rate of the currency pair.
- The current interest rates.

Time to Expiry

The time decay of an option is related to the time remaining in the option; in fact, it is proportional to the square root of the time remaining. The reason for this phenomenon is twofold:

1. The longer the time to maturity, the greater is the chance that the exchange rate moves such that the option will be exercised. The rate at which the premium diminishes as the option approaches expiry is called the "time decay"

and the rate of decay is exponential, that is, the option loses time value more quickly approaching expiry than it does earlier in its life. At expiry, the option will have only intrinsic value and no time value.

2. The time value can be thought of as "risk premium" or the cost to the writer of hedging the uncertainty of exercise.

Volatility

In essence, *volatility* is a measure of the variability (but not the direction) of the price of the underlying instrument, essentially the chances of an option's being exercised. It is defined as the annualized standard deviation of the natural log of the ratio of two successive prices.

Historical volatility is a measure of the standard deviation of the underlying instrument over a past period and is calculated from actual price movements by looking at intraday price changes and comparing this with the average (the standard deviation). The calculation is not affected by the absolute exchange rates, merely the change in price involved. Thus, for example, the starting and finishing points for two separate calculations could be exactly the same but could give two very different levels of volatility depending on how the exchange rate traded in between. Thus, if the market has traded up and down erratically, the reading will be high, and if instead it has gradually moved from one point to the other in even steps, then the reading will be lower.

Implied volatility is the volatility implied in the price of an option, that is, the volatility that is used to calculate an option price. Implied volatilities rise and fall with market forces and tend to reflect the level of activity anticipated in the future although supply and demand can at times be dominant factors. In the professional interbank market, two-way volatility prices are traded according to market perception and these volatilities are converted into premium using option models. Implied volatility is the only variable affecting the price of an

option that cannot be directly observed in the markets, thus leading to the typical variations in price inherent in any marketplace.

Actual volatility is the actual volatility that occurs during the life of an option. It is the difference between the actual volatility experienced during delta hedging and the implied volatility used to price an option at the outset, which determines if a trader makes or loses money on that option.

In summary, implied volatility is a timely measure, in that it reflects the market's perceptions today. On the other hand, historical volatility is a retrospective measure of volatility. This implies that it reflects how volatile the variable has been in the recent past. But it has to be remembered that it is a highly objective measure. Implied volatilities can be biased, especially if they are based upon options that are traded in a market with very little liquidity. Also, historical volatility can be calculated for any variable for which historical data is tracked.

Volatility affects the time value or risk premium of an option, as an increase in volatility increases the time value and thus the price of the option. Likewise, a decrease in volatility lowers the price of the option. For example, consider the position of the writer of an option, whereby, say, a bank sells an option to a client, giving the client the right to purchase dollars and sell Swiss francs in three months' time. In order to correctly hedge the position, consider what will happen in three months' time.

If the spot is above the strike price of the option, the client will exercise the option and the bank will be obliged to sell dollars and buy francs. However, if the spot is below the strike price, the client will allow the option to lapse. Hence, the bank's initial hedge for the option will be to purchase a proportion of dollars in the spot market against this potential short dollar position. If the spot subsequently rises, the likelihood of the option's being exercised will increase and so the initial hedge will be too small. Therefore, the bank will need to buy some more dollars, which it does at a rate worse than the

original rate at which the option was priced, thereby losing money. Conversely, if the spot rate falls, this makes the option less likely to be exercised and the bank will then find itself holding too many dollars and will have to sell them out at a lower price than where they were purchased, thus losing more money. These losses are called "hedging costs," and each time the spot market moves, the rehedging required will lose the bank money. In essence, the premium received by the writer is effectively the best estimate of these hedging costs over the life of the option.

Strike Price and Forward Rates

An option's time value is greatest when the strike price is at-the-money and the further in or out-of-the-money the strike price is, the lower the time value is. This can be explained by again considering the hedging costs. If the option is originally at-the-money, it is said to have a 50 delta and therefore the initial hedge will be to buy or sell half the principle amount of the option. The delta of the option can be thought of as the probability of exercise and so a 50 delta gives a 1-in-2 chance of exercise, that is, maximum uncertainty. As the spot moves, the delta will change and require readjusting of the hedge in the spot market. The change in delta (or gamma) is greater for a 50-delta option than for an option with a much higher or lower delta, for example 80- or 20-delta. This is because the likelihood of exercise, and therefore the amount of hedge required, changes more rapidly. Thus, less readjustment is required for these high and low delta options, and consequently, fewer hedging costs are incurred for the low and high delta options. This leads to lower levels of risk premium or time value for in-the-money and out-of-the-money options.

Interest Rates

The currency interest rate is another factor that affects option premiums. As premium is usually paid up front, it must be discounted to take

account of the interest that would be earned by putting the premium on deposit. Thus, the higher the domestic interest rate, the greater the discounting effect on the premium.

The effect of interest rate differential on the option premium is not intuitively obvious, yet it is one of the most important components of the premium for a currency option. If the dollar interest rate rises in relation to the interest rate of the foreign currency, the premium of a currency call option will increase in value. This is because holding a foreign currency and buying a currency call option are alternative investments. On the one hand, the investor will sell (borrow) dollars and buy (invest in) a foreign currency in order to take advantage of a rise in that foreign currency. On the other hand, the trader could just simply buy a currency call option. If the dollar interest rate rises, the cost of borrowing dollars will increase, which will make the alternative of buying a currency call option more attractive. Consequently, the premium will rise.

This can equally be explained in terms of the forward value of a currency. If the dollar interest rate rises in relation to the foreign currency interest rates, and the spot rate remains the same (unchanged), covered interest rate arbitrage will ensure that the forward rate of the foreign currency will rise relative to the spot. Therefore, the call option on that currency will also rise in value. Of course, the dollar interest rate might remain the same, but the interest rate of the foreign currency might fall. The effect on the interest rate differential and therefore on the value of the currency call option will remain the same, but the premium will rise.

The converse is true for currency put options, because an increase in the dollar interest rate in relation to the foreign currency interest rate will, given no change in the spot price, result in a rise in the forward value of the currency. Thus, the holder of a put option on the currency will see the premium fall. Buying a currency put option is an alternative strategy to borrowing in that currency and investing in dollars. Hence, a

rise in the dollar interest rate or a fall in the foreign currency interest rate makes the put option strategy less attractive, and the put premium will fall.

The effect of interest rate differential changes on currency option premiums can be summarized as follows:

- Assuming the spot rate remains unchanged, a rise in dollar interest rates relative to the foreign currency interest rate, or a fall in the foreign currency interest rate relative to the dollar interest rate, will increase the premium for a currency call option and decrease the premium for a currency put option.
- Assuming the spot rate remains the same, a fall in the dollar interest rate relative to the foreign currency interest rate, or a rise in the foreign currency interest rate relative to the dollar interest rate, will decrease the premium for a currency call option and increase the premium for a currency put option.

American versus European

For European options, intrinsic value is the value of an option relative to the outright forward market price; that is, it represents the difference between the strike price of the option and the forward rate at which one could transact today. Intrinsic value can be zero but is never negative. If the strike price of the option is more favorable than the current forward price, the option is in-the-money. If the strike price is equal to the forward rate, the option is at-the-money and if the strike price is less favorable than the outright forward, the option is out-of-the-money.

A similar definition applies for American-style options, except that the option's "moneyness" relative to the spot price also needs to be considered. Naturally, the cost of the option needs to be considered in order to achieve a profitable early exercise and this leads to a phenomenon peculiar to American options known as optimal exercise. This is the point at which it becomes profitable to exercise an

American option early, having taken account of the premium paid.

In fact, there are several occasions when it would be better to pay extra premium and buy a more expensive American-style option. For example:

1. When a trader is buying an option where the call currency has the higher interest rate and there is an expectation that the interest rate differential will widen significantly.
2. When a trader is buying an option where the interest rates are close to each other and there is an expectation that the call interest rate will move above the put interest rate.
3. When a trader is buying an out-of-the-money option with interest rates as in both of the above and there is an expectation for it to move significantly into the money, then the American-style option is more highly leveraged and will hence produce higher profits.

THE GREEKS

Traders extensively use *the "Greeks,"* a set of factor sensitivities, to quantify the exposure of portfolios that contain options. Each measures how the portfolio's market value should respond to a change in some variable. For speculative purposes, the value of an option needs to be known on a continual basis, and more importantly, the factors that change an option's value need to be understood. In analyzing an option risk (or value), the market norm is to use letters of the Greek alphabet. Not surprisingly, they are often referred to as the "Greeks," and they include delta, vega/kappa, theta, gamma, and rho. However, vega is not in the Greek alphabet, but is named after a star in the constellation Lyra. Sometimes, vega has also been referred to as kappa. Also, four of the five are risk metrics. The exception here is theta, because the passage of time is certain and thus entails no risk.

These major Greeks, which measure these risks and need to be taken into account before taking any option positions, are:

Vega/Kappa	Theta	Delta	Gamma	Rho
Measures the impact of a change in volatility	Measures the impact of a change in time remaining	Measures the impact of a change in the price of the underlying	Measures the rate of change in delta	Measures the sensitivity to an applicable interest rate

Delta

When option traders sell or buy a currency option, they will use the foreign exchange market to hedge the exposure. The most common type of hedging is delta hedging.

Delta is the change in premium per change in the underlying. Technically, the underlying is the forward outright rate but as the option-pricing model assumes constant interest rates, this is often calculated using spot. For example, if an option has a delta of 25 and spot moved 100 basis points, then the option price gain/loss would be 25 basis points. For this reason, delta is sometimes thought of as representing the "spot-sensitive" amount of the option.

Also, delta can be thought of as the estimated probability of exercise of the option. As the option-pricing model assumes an outcome profile based around the forward outright rate, an at-the-money option has a delta of 50%. It falls for out-of-the-money options and increases for in-the-money options, but the change is non-linear, in that it changes much faster when the option is close-to-the-money.

Turning to calculus for the formal definition of delta, let t be the current time. Let 0p and 0s be current values for the portfolio and underlier. Delta is the first partial derivative of a portfolio's value with respect to the value of the underlier:

$$\text{delta} = \frac{\partial {}^0p}{\partial {}^0s}$$

This technical definition leads to an approximation for the behavior of a portfolio.

$$\Delta^0 p \approx \text{delta} \Delta^0 s$$

where $\Delta^0 s$ is a small change in the underlier's current value, and $\Delta^0 p$ is the corresponding change in the portfolio's current value. This is called the delta approximation.

An option is said to be delta hedged if a position has been taken in the underlying in proportion to its delta. For example, if one is short a call option on an underlying with a face value of \$1 million and a delta of 0.25, a long position of \$250,000 in the underlying will leave one delta neutral with no exposure to changes in the price of the underlying, but only if these are infinitesimally small.

As the underlying market moves throughout the life of the option, the delta will change, thus requiring the underlying hedge to be adjusted. Once the initial hedge has been transacted, calls and puts behave in precisely the same way, in terms of the hedging required.

For example, an at-the-money sterling call/dollar put option in £10 million, with a strike price of 1.75, has an initial delta of 50. The option writer, therefore, buys £5 million in the spot market to hedge the option position. If the spot rises to 1.77, the delta will increase to, say, 60. Now, the writer needs to purchase an extra £1 million to attain delta neutrality. If the exchange rate then falls back again to the original rate, the option writer is overhedged and requires selling back £1 million in order to remain delta neutral. Clearly, as the option writer rehedges, losses will be incurred, which will increase as volatility increases.

Another example could be where a trader sells a dollar call/Swiss franc put at 1.5500 for six months for \$10 million. The trader's risk is that in six months, the option will be exercised and there will be a payout of dollars and a receipt of francs. The trader's hedge against this risk would therefore be to buy dollars and sell francs, thus hedging the delta amount because this represents the likelihood of exercise. If spot

is 1.5300 and the forward outright is 1.5345, then the trader's hedging, ignoring time movement, would look like that shown in the following table, as the forward rate changes:

Forward	Delta	Hedge	Total
1.5345	35	Buy \$3.5 million	+\$3.5 million
1.5500	50	Buy \$1.5 million	+\$5.0 million
1.5600	57	Buy \$0.7 million	+\$5.7 million
1.5200	30	Sell \$2.7 million	+\$3.0 million

Whether or not the trader loses money will depend on volatility. From the preceding table, it can be seen that hedging a short option position loses money, as the trader would be continually buying high and selling low. However, when the option was first sold, the trader received a premium for it, representing the estimated cost of hedging to the trader. If the volatility of the market is higher than the trader expected and then has to hedge more frequently, then the trader may lose more money hedging than originally gained on the premium. If, however, the market is less volatile than the assumption of the option price, the trader should lose less money hedging than received in premium and therefore make a profit overall.

If the trader had bought the option rather than sold it, the trader would then hope for increased volatility because the hedging exercise would be making money.

For example, the trader buys exactly the same options, a dollar call/Swiss franc put at 1.5500 in \$10 million. The trader's risk is now that there will be a long dollar position in six months, so the hedge will be to sell dollars and buy francs. As the forward outright rate moves, however, the delta of the option will move in exactly the same way as before. This follows as the option is the same and the delta does not depend on who owns the option. In this case, therefore, the trader will be buying low and selling high and making money on the hedging. Just as before, this makes sense, as the trader originally paid out a premium to buy the option, so the hedging is making back that premium. This time,

the trader has bought volatility and hopes that volatility will in fact be higher than the rate at which the option was bought for. If it is, the trader will make more money hedging than was paid out in premium.

Hence, buying and selling volatility is like any other product in that there is a wish to buy at a low rate and sell at a higher rate to make a profit.

As another example, consider a short sterling call at a 1.8100 position at 342 points. The loss profile corresponds to the loss profile on a short sterling cash position. Thus, a hedge on a short sterling call position would be to buy sterling cash. The value of the option will go up with sterling going up, but it is not a one-to-one relationship.

The delta ratio indicates the increase in value of the option for every increase in value of one point on the cash market. Thus, the following rules on delta can be established. On a call option, delta will range from 0% when out-of-the-money to 50% at-the-money to 100% when deep in-the-money. Conversely, the delta of a put option goes from 0% when out-of-the-money to -50% at-the-money to -100% when deep in-the-money.

In the preceding example, the delta of the option is, say, 45%, which means that to hedge the position, an amount of sterling of 45% of the face value of the option will have to be bought. Therefore, if the option is for £1 million, a move up of 50 points on the rate will result in a loss of:

$$£1 \text{ million} \times 0.0050 \times 45\% = \$2,250$$

This will be offset by the long cash position of:

$$450,000 \times 0.0050 = \$2,250$$

The delta of an option does not remain constant and the new delta of this position is, say, 47%. In order to maintain a delta-neutral position, the trader will have to buy another £20,000. Such a hedging strategy will enable the trader

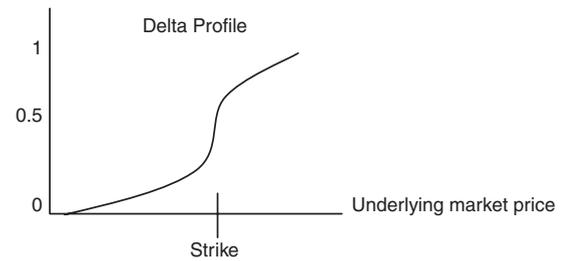

Figure 3 Delta Profile

to keep the premium received initially when selling the option.

Figure 3 shows that delta is the gradient of the tangent of the curve of the premium in relation to the cash prices. This will also reveal that delta will move more rapidly for an option with a short remaining life than for an option with a long remaining life.

In conclusion, basically, the delta of an option will change if any factor which influences the potential probability of exercise changes. These include spot price, volatility, time, and interest rates. Option trades use the delta as a guide to hedging. Taken simply, if a bank is short one option with a delta of 50%, the bank will hedge only half of the nominal amount of the option as it only has a 50% chance of being exercised. This is known as “delta hedging.” This is a simplistic example, and, in reality, banks have large option books, which they hedge on a daily basis, but the principal applies no matter what the size of the portfolio.

Also, there are three points to keep in mind with delta:

1. Delta tends to increase as it gets closer to expiration for near or at-the-money options.
2. Delta is not a constant.
3. Delta is subject to change given changes in implied volatility.

Gamma

The rate of change of delta is called gamma, and it will give a measure of the amount of change in the delta for a given change in the cash price.

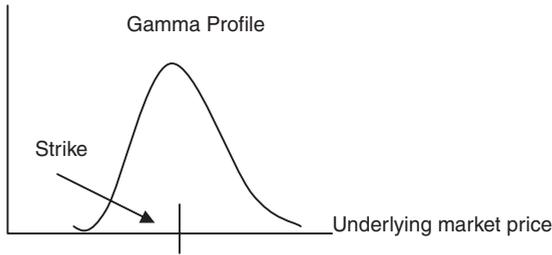

Figure 4 Gamma Profile

Therefore, it will provide an estimate of how much it will cost to delta hedge.

The cost of rebalancing the hedge is a consequence of the curvature of the premium curve against cash prices. The curvature is greatest at-the-money and reduces when in-the-money or out-of-the-money. This is shown in Figure 4.

A short option position is called gamma negative. The higher the gamma, the less stable is the delta hedge. A first conclusion is that it is more costly to hedge a short long-dated option position than a short position of short-dated options.

Thus, gamma is the change in delta per change in the underlying and is important because the option model assumes that delta hedging is performed on a continuous basis. In practice, however, this is not possible, as the market gaps and the net amounts requiring further hedging would be too small to make it worthwhile. The gapping effect that has to be dealt with in hedging an option gives the risk proportional to the gamma of the option.

For a formal definition of gamma, again turn to calculus. Gamma is the second partial derivative of a portfolio's value 0p with respect to the value 0s of the underlier:

$$\text{gamma} = \frac{\partial^2 p}{\partial^2 s}$$

By incorporating gamma, there can be an improvement to the approximation for how the portfolio's value should change in response to small changes in the underlier's value:

$$\Delta^0 p \approx \frac{\text{gamma}}{2} \Delta^0 s^2 + \text{delta} \Delta^0 s$$

This is called the delta-gamma approximation.

An option's gamma is at its greatest when an option is at-the-money and decreases as the price of the underlying moves further away from the strike price. Therefore, gamma is U-shaped and is also greater for short-term options than for long-term options.

By convention, gamma can be expressed in two ways:

1. A gamma of, say, 5.23 will mean that for 1% change in the underlying price the delta will change by 5.23 units. That is, from 50% to 55.23%.
2. A gamma of 3% will mean that for a one unit change in the underlying price, the delta will change by 3%, for example from 50% to 51.5%.

As an example of gamma hedging, as the forward outright rate moves from 1.5600 to 1.5200, the delta of the option moves from 57 to 30. The size of movement of the delta given this movement of the underlying is the gamma of the option by the definition "gamma is the change in delta per change in the underlying." The hedging the trader was required to do was to sell \$1.7 million. In practice, the trader sold the full amount at a rate of 1.5200. If the trader were able to hedge continuously as the model assumes, the trader would have sold the same amount, that is, \$1.7 million, but at an average rate of 1.5450. This would obviously have been more profitable. From this example, it can be seen that the gapping effect works against the trader when there is a short options position (and therefore short gamma), and a repetition of the exercise would show that the gapping is in the trader's favor if a long options position were being held (and gamma).

The value of gamma is, therefore, very important in determining sensitivity to spot movement and this gapping effect.

However, gamma is not the same for all options. Gamma is greater for short-term options

than for long-term options. For example, assume a dollar call/Swiss franc put option with a strike of 1.5500 and that there is one second to get to expiry. If the spot at the time is 1.5501, the option is extremely likely to be exercised and the delta will be 100. If, in that second, the spot moved to 1.5499, the option would not, in fact, be exercised and the delta would move to 0. Here, it can be seen that a 0.0002 move in spot produced a change in delta from 100 to 0. If it were the same option but there was one year to maturity, a movement of 0.0002 in spot would not significantly alter the likelihood that the option would be exercised; that is, the delta would not change noticeably.

Gamma is greater for at-the-money options than for options with deltas above or below 50. Assume an extreme example to see this effect, using the same option of a dollar call/Swiss franc put with a strike of 1.5500, and there is a second to go before expiry. If the spot is at 1.5500 and thus the option has a delta of 50, there would be the same situation as before when a 0.0001 movement in spot created a movement of 50 in the delta. If, however, the spot were at 1.5200, the delta of the option would be 0, and a movement even as large as 0.0200 would not increase that delta.

In conclusion, gamma is seen as a second-generation derivative, where the others considered are regarded as first-generation derivatives in the pricing of an option, in that the others all consider the change that an external effect has on an option's value, such as change in spot. However, gamma measures the rate of change of the delta itself. Therefore, it is literally the delta of the delta. Since the delta is the key pricing tool used by market participants in controlling the portfolio risk, to be able to work out the rate of change of this risk is very useful. Hence, gamma is a very important part of any option portfolio and is affected by three different factors: spot movement, time to maturity, and volatility.

Also, the three points to keep in mind with gamma are:

1. Gamma is smallest for deep out-of-the-money and deep in-the-money options.
2. Gamma is highest when the option gets near-the-money.
3. Gamma is positive for long options and negative for short options.

Theta

Theta is the depreciation of the time value element of the premium, that is, it measures the effect on an option's price of a one-day decrease in the time to expiration. The more the market and strike prices diverge, the less effect theta has on an option's price. Obviously, if you are the holder of an option, this effect will diminish the value of the option over time, but if you are the seller (the writer) of the option, the effect will be in your favor, as the option will cost less to purchase. Theta is nonlinear, meaning that its value accelerates as the option approaches maturity. Positive gamma is generally associated with negative theta and vice versa.

The rate at which the time value decays with respect to time is expressed as hundredths of a percent per unit of time (day/week). Obviously, the theta factor plays in favor of a short option position. Shorter-dated options have larger thetas as do those at-the-money. This effect will give rise to trading strategies referred to as a calendar spread.

To determine theta, assume t denotes time, and let ${}^t p$ denote the portfolio's value at time t . Formally, theta is the partial derivative of the portfolio's value with respect to time:

$$\text{theta} = \frac{\partial {}^t p}{\partial t}$$

where the derivative is evaluated at time $t = 0$. This technical definition leads to an approximation for the behavior of a portfolio.

$$\Delta {}^t p \approx \text{theta} \Delta t$$

where Δt is a small interval of time, and $\Delta {}^t p$ is the change in the portfolio's value that will

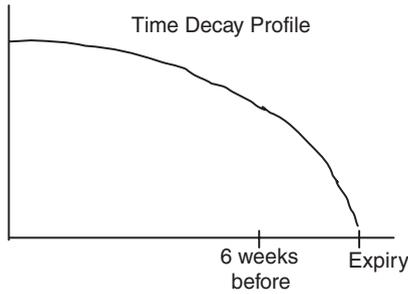

Figure 5 Time Decay Profile

occur during that interval, assuming all other market variables remain the same.

The delta of an option does have an influence on the time decay of an option because the time value element of an option total value is maximum for at-the-money options. As the delta increases or decreases, the time value of the option decreases. Obviously, for options where there is very little time value, there will be very little time decay. If there is any doubt about which date to choose for an option maturity, as can be seen in Figure 5, there is little increase in time value for days at the far end of the option. To buy a slightly longer option, therefore, will not cost much more. However, if a trader waits until the option expires and then has to buy another option to cover the final period, the additional cost could be substantially more. For this reason, buying an option for the longest period needed is recommended.

In actual practice, traders do not use theta, but it is an important conceptual dimension. However, some additional points of note are:

1. Theta can be very high for out-of-the-money options if they contain a lot of implied volatility.
2. Theta is typically highest for at-the-money options.
3. Theta will increase sharply in the last few weeks of trading and can severely undermine a long option holder's position, especially if implied volatility is on the decline at the same time.

Vega

Vega, sometimes also called kappa, quantifies risk exposure to implied volatility changes. Vega tells us approximately how much an option price will increase or decrease given an increase or decrease in the level of implied volatility. Option sellers benefit from a fall in implied volatility, while option buyers benefit from an increase in implied volatility. Vega is greatest for at-the-money options and increases with the time to maturity. This is the case because the longer the time to maturity, the greater the possibility of exchange rate movements and, therefore, the greater the sensitivity of the option price to a change in volatility.

Vega is the first partial derivative of a portfolio's value 0p with respect to the value ${}^0\sigma$ of implied volatility. This technical definition leads to an approximation for the behavior of a portfolio.

$$\Delta^0 p \approx \text{vega} \Delta^0 \sigma$$

where, here, $\Delta^0 \sigma$ is a small change in the implied volatility from its current value, and Δp is the corresponding change in the portfolio's value.

Thus, the more volatile the underlying price the more expensive the option will become because of the uncertainty element. The ratio of how much the value of the premium changes for a 1% change in volatility is vega. Longer-dated options have higher vegas and at-the-money options have higher vegas. It is expressed as a percentage change of dollars for a 1% change of volatility. For example, a vega of 1.0 means the option premium will appreciate by 1% in dollar or sterling terms.

Rho

It is generally considered to be the least important of the Greeks, but nevertheless any option, be it a single position or a large portfolio, will be exposed to such a risk. This is because with over-the-counter European-style

options, the price (in part) is derived from the forward rate. Therefore, if either of the two interest rates of the currency pair in the option should change, so the forward and hence the price will change. This can happen without a move in the spot price.

In formulating rho, let 0p and 0r be current values for the portfolio and underlier. Formally, rho is the partial derivative of the portfolio's value with respect to the risk-free rate:

$$\text{rho} = \frac{\partial {}^0p}{\partial {}^0r}$$

This technical definition leads to an approximation for the behavior of a portfolio.

$$\Delta {}^0p \approx \text{rho} \Delta {}^0r$$

where $\Delta {}^0r$ is a small change in the risk-free rate, and $\Delta {}^0p$ is the corresponding change in the portfolio's value.

In summary, rho is the general term used for interest rate risk, but it is broken down further. Rho usually refers to the base currency interest rate (usually dollars), and phi relates to the traded currency interest rates (e.g., Swiss francs or Japanese yen).

Beta and Omega

Some other Greek letters that are used do not actually measure an option's value but are more geared to looking at the use of options or risks associated with valuation methods. Briefly, they include beta and omega.

Beta represents the risk involved in hedging one currency pair against another, especially when sometimes currency pairs have a high correlation, for example, within the old European Monetary System (EMS) with the deutsch mark and the French franc. Some traders that had a dollar against the franc position would have been happier hedging this exposure in the more liquid dollar against the mark market because it fairly closely correlated to the franc. The risk here would have been if the mark against the franc correlation had started to weaken.

Omega measures the translation profit/loss risk assumed by trading in currency pairs (which result in profits/losses in those two currencies) that are not the same as the reporting base currency for accounting purposes. An example would be an American bank that gets profits for its sterling against Swiss franc trades in either sterling or francs, yet has to convert these to dollars for the balance sheet.

KEY POINTS

- The generally accepted pricing basis for options today is the Black-Scholes formula, which was devised in the early 1970s to provide a "fair value" for equity options. However, the foreign exchange markets needed something to take account of interest rates and the fact that there are no dividends due on currencies.
- Various adaptations of the Black-Scholes model emerged, of which the most popular one used today is the Garman-Kohlhagen system. This method makes allowances for the interest rates of the respective currencies and the fact that a currency can trade at a discount or premium forward relative to the other currency.
- American-style options differ due to the possibility of early exercise. The Cox-Ross-Rubenstein model is the generally accepted method for these, but they do not feature heavily in the over-the-counter market.
- Overall, the industry norm is to use the Black-Scholes formula adapted by Garman-Kohlhagen for valuing over-the-counter European-style currency options.
- The factors required to price an option include: (1) currency pair; (2) call or put; (3) strike rate; (4) amount; (5) style (European or American); (6) expiration date and time (New York expiry or Tokyo expiry); (7) prevailing spot rate; (8) interest rates for both currencies; (9) foreign exchange swap rate (calculated from the information in the

previous factor); and (10) volatility of the currency pair.

- The six factors chosen by the potential buyer/seller of the option are the currency pair, call or put, strike rate, amount, style, and expiration date and time. The prevailing spot rate, interest rates for both currencies, and foreign exchange swap rate are given by the market. The volatility of the currency pair is the only unknown factor, representing the anticipated market volatility expected for the life of the option, and is determined using the option pricing models discussed in this entry.

Abstract: Credit default swaps are the most popular of all the credit derivative contracts traded. Their purpose is to provide financial protection against losses incurred following a credit event of a corporate or sovereign reference entity. Replication arguments attempting to link credit default swaps to the price of the underlying credits are generally used by the market as a first estimate for determining the price at which a credit default swap should trade. The replication argument, however, is dependent on the existence of same maturity and same seniority floating rate bonds. Even if such securities do exist, contractual differences between CDS and bonds can weaken the replication relationship. Over the past decade, the increased liquidity of the CDS market has meant that in some cases, it, and not the bond market, is the place where credit price discovery occurs. Despite this it still necessary to have a CDS valuation model for the valuation and risk-management of existing positions.

Credit default swaps (CDSs), or simply default swaps, provide an efficient credit-risk transferring financial instrument. Their over-the-counter nature also makes them infinitely customizable, thereby overcoming many of the limitations of the traditional credit market instruments such as lack of availability of instruments with the required maturity or seniority. Increasing standardization and familiarization with the legal framework has made capital market participants more willing to enter into default swap transactions as have developments in credit modeling and pricing that have made

it possible to mark-to-market and hedge default swap positions.

Bonds are the main source of liquidity in the credit markets, especially in the United States. In the early years of the CDS market, replication arguments that attempted to link CDSs to bonds were therefore generally used by the market as a first estimate for determining the price at which CDSs should trade. Nowadays, the greater liquidity of the CDS market means that it is often the place where price discovery occurs and can at times lead the cash credit bond market. So while the replication relationship is still

important, it is now a two-way process with bond traders looking at CDS prices and CDS traders looking at bond prices, all watching to see if the replication relationship breaks down to the extent that any dislocation becomes arbitrageable, at which point they will step in and enter into positions to profit from the dislocation. If done in a material size, the effect of such an action should be to realign the two markets. However, the replication argument is not exact, as it is based on a number of assumptions that often break down in practice. Market participants who wish to price CDSs and examine relative value opportunities need to understand replication and its assumptions. We discuss the replication approach in this entry.

However, replication only provides a starting point for quoting CDS spreads. It does not allow traders to actually mark to market their existing CDS positions. By definition, marking a CDS position to market must involve pricing it off the current market CDS spread curve—a set of CDS spreads quoted for different maturities. The main objective of this chapter will be to explain how to determine the CDS spread, what factors affect its pricing, and how to mark-to-market CDSs. We show that this requires a model and set out the standard model that is used by the market.

DEFAULT SWAPS

In a standard CDS contract one party pays a regular fee to another to purchase credit protection to cover the loss of the face value of an asset following a credit event. The company (or sovereign) to which the triggering of the credit event is linked is known as the reference entity.

This protection lasts until some specified maturity date which falls on the 20th of either March, June, September or December, typically five years from the trade date. To pay for this protection, the protection buyer makes a regular stream of payments. These are quoted in terms of an annualized percentage known as the CDS spread. These payments are typically paid quarterly according to an Actual 360 ba-

sis convention and are collectively known as the premium leg. Payments occur until maturity of the contract or a credit event occurs, whichever happens first. The protection buyer will also pay the protection seller the fraction of the coupon which has accrued since the previous premium payment date.

If a credit event does occur before the maturity date of the contract, there is a payment by the protection seller, known as the protection leg. There are two ways to settle the payment of the protection leg: physical settlement and cash settlement. The form of settlement is specified at the time of the ISDA organised auction used to determine the final recovery price of the deliverable obligations. This can take the form of physical or cash settlement and one of the purposes of the auction is to ensure that both have the same economic value.

- **Physical settlement:** Following the ISDA auction, a protection buyer who elects for physical settlement will submit a facevalue amount of bonds into the auction and receive a payment of 100 on the same facevalue. A protection seller who elects for physical settlement will end up receiving a deliverable obligation and paying par. In general there is a choice of deliverable obligations from which the protection buyer can choose. These deliverable obligations will satisfy a certain number of characteristics that typically include restrictions on the maturity of the deliverable obligations and the requirement that they be pari passu—most default swaps are linked to senior unsecured debt. Typically, they include both bonds and loans. If deliverable obligations trade with different prices following a credit event, which they are most likely to do if the credit event is a restructuring, the protection buyer can take advantage of this situation by buying and delivering the cheapest deliverable. The protection buyer is therefore long a cheapest to deliver (CTD) option.
- **Cash settlement:** A protection buyer who opts for cash settlement receives par minus the recovery price on his face value. The

recovery price is the one determined by the ISDA auction. The protection seller pays par minus the same recovery price.

CDS spreads are typically quoted for a variety of maturities with most liquidity at the five-year maturity followed by the three-year and seven-year maturities. The bid is the spread at which the dealer is willing to buy protection, while the offer is the spread at which the dealer is willing to sell protection. Clearly, the bid spread will be less than the offer spread. Note that this is opposite to the convention for bonds where the bid spread is the spread at which the dealer is willing to buy the bond and this will be higher than the offer spread. This is because the buyer of a bond is selling protection, while the buyer of a CDS is buying protection.

Illustration

Suppose a protection buyer purchases 5-year protection on a company at a default swap spread of 200bp. The face value of the protection is \$10 million. The protection buyer therefore makes quarterly payments approximately equal to $\$10 \text{ million} \times 0.02 \times 0.25 = \$50,000$. (The exact payment amount is a function of the calendar and basis convention used.) After a short period the reference entity suffers a credit event. Assuming that the subsequent ISDA auction which takes place within 2 months of the credit event determines a recovery price of \$35 per \$100 of face value, the payments are as follows:

- The protection seller compensates the protection seller for the loss on the face value of the asset received by the protection buyer. This is equal to $\$10 \text{ million} \times (100\% - 35\%) = \6.5 million .
- The protection buyer pays the accrued premium from the previous premium payment date to time of the credit event. For example, if the credit event occurs after a month then the protection buyer pays approximately $\$10 \text{ million} \times 0.02 \times 1/12 = \$16,666$ of premium accrued. Note that this is the standard for corporate reference entity linked default swaps.

The Mechanics of Settlement

The timeline around the physical settlement of a CDS following a *credit event* consists of three steps:

1. A CDS market participant who has previously signed up to the ISDA protocols submits a request to the ISDA determinations committee asking whether or not a credit event has occurred on a specified reference entity. The event must be evidenced by at least two sources of publicly available information (e.g., a news article on Reuters, the *Wall Street Journal*, the *Financial Times* or some other recognized publication or electronic information service). The determinations committee, which consists of both buy and sell-side representation then has to decide whether or not the credit event has occurred. An 80% supermajority is needed to approve any decision. If it is determined that a credit event has occurred, the process leading to the ISDA auction is then begun.
2. The ISDA then begins compiling a list of the deliverable obligations and publishes the details of the auction which will take place in order to determine the recovery price. If the credit event is a bankruptcy or a failure to pay then CDS contracts are automatically triggered. However if the event is a restructuring, CDS protection buyers can decide whether to trigger their contract or not – if they decide not to trigger then the contract can be used later if a bankruptcy or failure to pay occurs. In Europe, the settlement of a restructuring event is also complicated by the fact that standard CDS contracts with different maturities can have different baskets of deliverable obligations and separate auctions will be needed to determine their final recovery price for each basket.
3. The auction takes place. CDS market participants who have positions in the triggered contracts need to decide whether or not to settle physically or in cash. Buyers and sellers of CDS protection can choose physical settlement even if their trade counterparty

chose cash settlement, and vice-versa. The various dealers through whom market participants trade then bring all of these positions plus their own positions into an auction at the end of which only the net position – the net open interest – will be transferred, thereby averting any short squeeze which may be caused if the gross notional of CDS positions exceeds the outstanding notional of deliverable obligations. Dealers can then submit bids or offers on the net open interest of physical obligations, which may be long or short. At the end of this auction procedure, a recovery price is determined. All CDS contracts are then automatically settled at this recovery price.

As a result, the maximum delay between notice of a credit event and the actual payment of the protection is approximately 72 calendar days.

CREDIT EVENTS

The most important section of the documentation for a default swap is what the parties to the contract agree constitutes a credit event that will trigger a payment by the protection seller to the protection buyer. Definitions for credit events are provided by the International Swap and Derivatives Association (ISDA). First published in 1999, there have been periodic updates and revisions of these definitions. The most recent, and one of the most important updates of the ISDA documentation for credit default swaps was the introduction of the Big Bang protocol in 2009. These were a response to the Financial Crisis of 2008 and were intended to streamline the process of determining and settling a credit event. They were also intended to enable the migration of CDS trades to centralised counterparties by increasing fungibility.

ISDA Credit Event Definitions

Of the eight possible credit events referred to in the *1999 ISDA Credit Derivative Definitions*, the ones typically used within most contracts are listed in Table 1. In terms of which are used,

Table 1 Credit Events Typically Used within Most CDS Contracts

Credit Event	Description
Bankruptcy	Corporate becomes insolvent or is unable to pay its debts. The bankruptcy event is of course not relevant for sovereign issuers.
Failure to pay	Failure of the reference entity to make due payments, taking into account some grace period to prevent accidental, triggering due to administrative error.
Restructuring	Changes in the debt obligations of the reference creditor but excluding those that are not associated with credit deterioration such as a renegotiation of more favorable terms.
Obligation acceleration/ obligation default	Obligations have become due and payable earlier than they would have been due to default or similar condition. Obligations have become capable of being defined due and payable earlier than they would have been due to default or similar condition. This is the more encompassing definition and so is preferred by the protection buyer.
Repudiation/ moratorium	A reference entity or government authority rejects or challenges the validity of the obligations.

Source: ISDA.

the market distinguishes between corporate- and sovereign-linked CDSs. For corporate-linked CDSs the market standard is to use just three credit events—bankruptcy, failure to pay, and restructuring. For sovereign-linked CDSs, obligation acceleration/default and repudiation/moratorium are also included.

Restructuring Controversy

Restructuring means a waiver, deferral, restructuring, rescheduling, standstill, moratorium, exchange of obligations, or other adjustment with respect to any obligation of the reference entity such that the holders of those obligations are materially worse off from either an economic, credit, or risk perspective. It has been the most controversial credit event that may be included in a default swap.

In bankruptcy or failure to pay, *pari passu* assets trade at or close to the same recovery value. But restructuring is different. Following a restructuring, debt continues to trade. Short-dated bonds trade at higher prices than longer-dated bonds, bonds with large coupons trade at a higher price than bonds with low coupon. Loans, which are typically also deliverable, tend to trade at higher prices than bonds due to their additional covenants.

This makes the delivery option that is embedded in a default swap potentially valuable. A protection buyer hedging a short-dated high coupon asset may find that following a restructuring credit event it is trading at, say, \$80 while another longer-dated deliverable may be trading at \$65. By selling the \$80 asset, purchasing the \$65 asset, and delivering it into the CDS, the protection buyer may make a \$15 windfall gain out of the delivery option. However, this gain is made at the expense of the protection seller who has to take ownership of the \$65 asset in return for a payment of par.

Such a situation arose in the summer of 2000 when the U.S. insurer Consecro restructured its debt. At that time, the range of deliverable obligations following a restructuring event was the same as those used for bankruptcy or failure to pay. This meant that bonds or loans with a maximum maturity of 30 years could be delivered. Protection sellers were displeased at being delivered long-dated low-priced bonds in the price range 65 to 80 by banks who held much higher-priced short-term loans. In addition, it was believed that there was a conflict of interest—banks who exercised their default swaps had also been party to the restructuring of Consecro's debt.

The results of this experience led to the market discussing a restructuring supplement to the standard ISDA documentation. This was completed on May 11, 2001, and introduced a new restructuring definition called modified restructuring (*mod-re*). The essence of this was to reduce the range of deliverable obligations following a restructuring event and so limit the value of the delivery option.

Although adopted by the North American market between 2002 and 2009, this standard has now become redundant for the standard North American contract (SNAC) since restructuring is no longer one of the standard triggering credit events. Europe has retained the restructuring credit event. However the basket of allowed deliverable obligations is determined by the Modified Modified Restructuring clause which effectively limits the maturity of these obligations to the greater of the maturity of the CDS contract and 60 months. Credit default swaps linked to Asian corporate credits continue to include restructuring as a credit event. They also retain the old style rules about what can be delivered, allowing all bonds and loans of the appropriate seniority and with a maximum maturity of 30 years. A summary description of the different standard market contracts by geographical region is shown in Table 2.

Where the same credit trades with different restructuring conventions, these different contract standards should be reflected in the quoted market spreads. For example,

Table 2 Different Restructuring Standards by geographic region.

Region	Description
North America	The standard North American contract (SNAC) now trades without restructuring as a credit event.
Europe	Both CDS and CDS indices trade with bankruptcy, failure to pay and restructuring. In the case of restructuring, the deliverable obligations are determined according to the Modified Modified Restructuring clause which limits the maturity of deliverables to the maximum of the maturity of the CDS and 60 months.
Asia	Both CDS and CDS indices trade with bankruptcy, failure to pay and restructuring. Following a restructuring event the only limit on deliverables is the old-style limit of a maximum maturity of 30 years.

Source: ISDA.

modified-modified restructuring allows the protection buyer to have a broader range of deliverables than modified restructuring. This means that the value of the delivery option is greater for mod-mod-re than for mod-re and so the protection should trade at a wider spread for the more valuable delivery option. More generally, there should be a strict theoretical relationship between these spread levels of¹

$$\text{Spread}_{\text{Old-Re}} > \text{Spread}_{\text{Mod-Mod-Re}} > \text{Spread}_{\text{Mod-Re}} > \text{Spread}_{\text{No-Re}}$$

In this entry, the aim is not to determine what the spread differences should be, but to price contracts of a given type given the corresponding curve of market spreads.

Credit Events and Implementation of Default Swap Pricing Models

In the pricing model presented in this entry, we refer to “default.” By this we mean any of the credit events included in the CDS contract. This means that the value of a contract will depend on which credit events are included in a particular trade.

While the model presented handles any of the credit events that may be selected by the parties to a trade, the data required are typically drawn from databases that collect defaults defined in a different way than those set forth by ISDA credit event definitions. For example, major studies regarding default rates and recovery rates, as well as default times, define default in terms of the legal definition of default. In contrast, consider restructuring. Suppose that full restructuring is included in a trade as a credit event. Then a reduction in a reference obligation’s interest rate that is material is a credit event. In fact, actions by lenders to modify the terms of a reference obligation without a bankruptcy proceeding are not uncommon. Yet, they are not included (or even known) to researchers who compile data on defaults.

The key point is that in the implementation stage, the inputs must be modified based on the credit events included in a trade.

PRICING CREDIT DEFAULT SWAPS BY STATIC REPLICATION

There is a fundamental relationship between the *default swap* market and the cash market in the sense that a default swap can be shown as being economically equivalent to a combination of cash bonds. This cash-CDS relationship means that determination of the appropriate default swap spread for a particular credit usually begins by observing the London Interbank Offered Rate (LIBOR) spread at which bonds of that issuer trade. The usual comparison is to look at what is called the *par asset swap spread* of a bond of a similar maturity to the default swap contract. This is the spread over LIBOR paid by a package containing a fixed-rate bond and interest rate swap purchased at par. This spread can easily be calculated.²

Since 2009, CDS contracts have traded with fixed premiums. Prior to this, any new CDS contract would have its premium set at initiation so that the contract would have zero initial value. In order to facilitate moves towards a centralised counterparty for CDS, in 2009 the market decided that all contracts on a specific reference entity, regardless of their maturity and when they were traded will trade with the same fixed premium. The value of this fixed premium is different for different reference entities. In the US it is 100bp for investment grade credits and 500bp for high-yield credits. A similar convention exists in Europe with additional spreads levels. The effect of this is that CDS contracts no longer have zero value at initiation. This is actually not a radical change – it simply means that new contracts have to be valued in the same way that seasoned CDS contracts were valued in the past. However, it does mean that the old CDS-bond static replication argument becomes less realisable.

Since it is a fixed number through time, the premium spread on the CDS linked to some reference entity no longer reflects the market implied credit risk of the reference entity at the time of the trade. That information is now

embedded in the upfront cost of the CDS. But this cost is not a spread measure and is difficult to use to compare the market implied credit risk across different credits and different maturities. Instead, the market has created a new spread measure known as the par CDS spread. This is defined as the coupon on a fictional CDS which would give it a zero initial value today. It is the old CDS premium now reborn as a spread measure. The following static replication argument is therefore based on such a fictional CDS contract where the spread S is set so that the contract has zero initial value. The reason for doing this is that we wish to understand the relationship between this par spread and the par asset swap spread. Note also that the standard model which we will describe later is the mechanism used to convert the upfront cost of a CDS contract to a par spread and vice-versa.

The premium payments in a default swap contract are defined in terms of a default swap spread, S , which is paid periodically on the protected notional until maturity or a credit event. It is possible to show that the default swap spread can, to a first approximation, be proxied by a par floater bond spread (the spread to LIBOR at which the reference entity can issue a floating rate note of the same maturity at a price of par) or the asset swap spread of an asset of the same maturity provided it trades close to par.

To see this, consider a strategy in which an investor buys a par floater issued by the reference entity with maturity T . The investor can hedge the credit risk of the par floater by purchasing protection to the same maturity date. Suppose this par floater (or asset swap on a par asset) pays a coupon of LIBOR plus F . Default of the par floater triggers the default swap, as both contracts are written on the same reference entity. With this portfolio the investor is effectively holding a default-free investment, ignoring counterparty risk.

The purchase of the asset for par may be funded on balance sheet or on repo—in which case we make the assumption that the repo rate can be locked in to the bond's maturity. The resulting funding cost of the asset is LIBOR plus

B , assumed to be paid on the same dates as the default swap spread S . Consider what happens in the following scenarios:

No credit event—The hedge is unwound at the bond maturity at no cost since the protection buyer receives the par redemption from the asset and uses it to repay the borrowed par amount.

Credit event—The protection buyer delivers the reference asset to the protection seller in return for par. If we assume that the credit event occurs immediately following a coupon payment date, then the cost of closing out the funding is par, which is repaid with this principal. The position is closed out with no net cost.

Both scenarios are shown in Figure 1. As the hedged investor has no credit risk within this strategy they should not earn (or lose) any excess spread. This implies that $S = F - B$; that is, the default swap spread should be equal, to the par floater spread minus the funding cost of the cash bond. For example, suppose the par floater pays LIBOR plus 25 basis points and the protection buyer funds the asset on balance sheet at LIBOR plus 10 basis points. For the protection buyer the breakeven default swap spread equals $F - B = 25 - 10 = 15$ basis points.

This analysis certainly shows that there should be a close relationship between cash and default swap spreads. However, the argument is not exact as it relies on several assumptions that could result in small but observable differences. Some are listed below:

1. We have assumed the existence of a par floater with the same maturity date as the default swap and that the coupon on the default swap contract has been set so that it has zero initial value.
2. We have assumed a common market-wide funding level of LIBOR + B . In practice, different market participants have different funding costs which therefore imply different spread levels.
3. We have assumed repo funding to term. Repo funding cannot usually be locked in

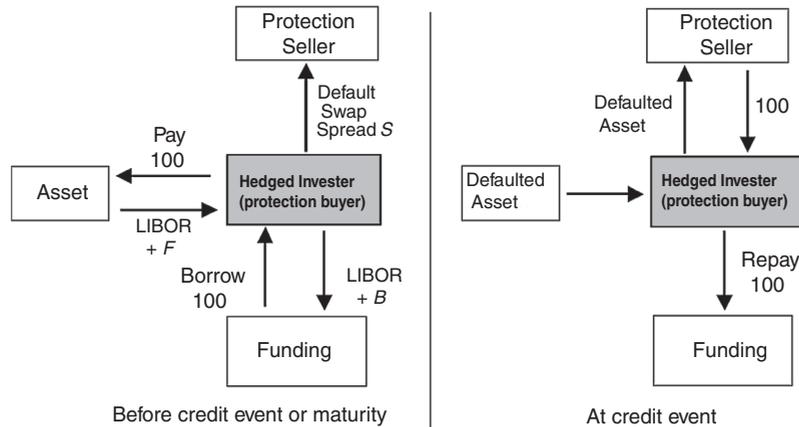

Figure 1 Theoretical Default Risk-Free Hedge for an Investor Who Buys Protection

to term but only for short periods of a couple of months only. One attraction of CDS is that unlike cash, they effectively lock in funding at LIBOR flat to maturity.

4. We have ignored accrued coupons. If the credit event occurs just before a coupon payment on the funding leg, the protection does not cover the loss of par plus coupon on the funding leg. We have also ignored the effect of the accrued CDS premium payment from the previous payment date.
5. We have assumed that the par floater is the cheapest-to-deliver asset.
6. We have ignored counterparty risk on the CDS. This is usually mitigated through the use of collateral.
7. Due to the difficulty of shorting cash bonds, any widespread market demand to go short a particular credit will first impact CDS, causing spreads to widen before cash.
8. For asset swaps the initial price of the asset must be close to par. This is because the loss on an asset swap of a bond trading with a full price P is about $P - R$. The credit risk is then only comparable to a default swap when the asset trades close to par.
9. We have ignored transaction costs.

Despite these assumptions, cash market spreads usually provide the starting point for where the default swap spreads should trade.

Empirically, there is a high correlation between the two spread levels. The difference between where and cash LIBOR spreads trade is known as the *default swap basis*, defined as

$$\text{Default swap basis} = S - F$$

There are now a significant number of market participants who actively trade the default swap basis, viewing it as a new relative value opportunity.³

PRICING OF A SINGLE-NAME CREDIT DEFAULT SWAP

Reduced versus Structural Models

To value credit derivatives it is necessary to be able to model the default risk, the recovery rate risk and the effect of interest rates. The two most commonly used approaches to model credit risk are structural models and reduced form models. The first structural model for credit-risky bonds was proposed by Black and Scholes (1973) who explained how equity owners hold a call option on the firm. After that Merton (1973 and 1974) extended the framework and analyzed the behavior of risky debt using the model.⁴

The second type of credit models, known as reduced-form models, are more recent.⁵ These models, most notably the Jarrow-Turnbull model and Duffie-Singleton model, do not look

inside the firm. Instead, they model directly the likelihood of a default occurring. Not only is the current probability of default modeled, they also attempt to model a “forward curve” of default probabilities that can be used to price instruments of varying maturities. Characterizing default as an event that occurs with a modeled probability has the effect of making default a surprise—the default event is a random event, which can suddenly occur at any time. All we know is its probability.

Reduced-form models are easy to calibrate to the term structure of CDS prices observed in the marketplace. This is known as working in an “arbitrage-free” framework. It is only by ensuring that a pricing model fits the market that a trader can be sure that he does not quote prices that expose him to any price arbitrages. The ability to quickly and easily calibrate to the entire CDS market is the major reason why reduced-form models are strongly favored by real-world practitioners in the credit derivatives markets for pricing. Structural-based models are used more for default prediction and credit risk management.

Increasingly, investors are seeking consistency between the markets that use different modeling approaches, as the interests in seeking arbitrage opportunities across various markets grows. Chen (2003) has demonstrated that all the reduced-form models described above can be regarded in a nonparametric framework. This nonparametric format makes the comparison of various models possible. Furthermore, as Chen contends, the nonparametric framework focuses the difference of various models on recovery.

The basic framework that underlies the reduced-form model is a binomial default process. There are two branches at each time point on the tree: default and survival. The branches that lead to default will terminate the contract and incur a recovery payment. The branches that lead to survival will continue the contract that will then face future defaults. This is a very general framework to describe how default oc-

curs and contract terminates. Various models differ in how the default probabilities are defined and the recovery is modeled.

Reduced form models use risk-neutral pricing to be able to calibrate to the market. In practice, we need to determine the risk-neutral probabilities in order to reprice the market and price other instruments not currently priced. In doing so, we do not need to know or even care about the real-world default probabilities.

Since in reality, a default can occur any time, to accurately value a default swap, we need a consistent methodology that describes the following: (1) when defaults occur, (2) how recovery is paid, and (3) how discounting is handled.

Survival Probability

Assume the risk-neutral probabilities exist. Then we can identify a series of risk-neutral *default probabilities* so that the weighted average of default and no-default payoffs can be discounted at the risk-free rate. The risk-free rate used in the pricing of CDS is LIBOR. This is because within a derivatives framework, the risk-free rate is close to the rate at which market dealers fund their hedges.

Assume $Q(t)$ to be the *survival probability* from now till some future time t . Then $Q(t) - Q(t + \tau)$ is the default probability between t and $t + \tau$ (that is, survive till t but default before $t + \tau$). Assume defaults can only be observed at multiples of τ . Then the total probability of default over the life of the CDS is the sum of all the per period default probabilities:

$$\sum_{j=1}^n Q[(j-1)\tau] - Q(j\tau) = 1 - Q(n\tau) = 1 - Q(T)$$

where $Q(0) = 1.0$ and $n\tau = T$, the maturity time of the CDS. It is no coincidence that the sum of the all the per-period default probabilities should equal one minus the total survival probability.

The survival probabilities have a useful application. A \$1 “risky” cash flow received at time t has a risk-neutral expected value of $Q(t)$ and a

present value of $P(t)Q(t)$ where P is the risk-free discount factor.

The value of the protection leg of a CDS is the present value of the payment of $(1 - R)$ at default. To take into account the timing of the default payment $(1 - R)$, we break the time to maturity into n intervals which correspond to the premium payment dates on the premium leg. This is a simple numerical approximation which works well given the quarterly payment convention of CDS. However a more exact model would break the time to maturity into monthly or even weekly time steps. For each time period we consider the probability of defaulting in each. The probability of defaulting in a forward interval $[(j - 1)\tau, j\tau]$ is given by

$$Q[(j - 1)\tau] - Q(j\tau) \quad (1)$$

We then discount the payment of $(1 - R)$ back to today by multiplying it by the risk-free discount factor $P(t)$. We then consider the likelihood of default occurring in all of the intervals by summing over all intervals. We therefore have

$$V = (1 - R) \sum_{j=1}^n P(j\tau) \{Q[(j - 1)\tau] - Q(j\tau)\} \quad (2)$$

where $R(\cdot)$ is the expected recovery rate determined by a CDS auction which takes place soon after a credit event rate.

In the above equation, it is implicitly assumed that the discount factor is independent of the survival probability. In reality, these two may be correlated—usually higher interest rates lead to more defaults because businesses suffer more from higher interest rates. To account for this we would need to introduce a stochastic probability and interest rate model. However, the effect of this correlation is almost negligible on the valuation of CDS and is further reduced by calibration. Equation (2) has no easy solution.⁶

Premium payments on the premium leg of a CDS terminate as soon as a credit event occurs. As a result the expected present value of the premium leg of the default swap is given by discounting each of the expected spread payments

by the risk-neutral discount factor weighted by the probability of surviving to each payment date. This is given by

$$S \sum_{j=1}^N \Delta_j P(j\tau) Q(j\tau)$$

where Δ_j is the corresponding year fraction in the appropriate basis convention (typically actual 360). By definition the value of the default swap spread is the value at which the premium and protection legs have the same present value. Hence, we have

$$V = S \sum_{j=1}^n \Delta_j P(j\tau) Q(j\tau) \quad (3)$$

giving

$$S = \frac{V}{\sum_{j=1}^n \Delta_j P(j\tau) Q(j\tau)}$$

Figure 2 depicts the general default and recovery structure. The payoff upon default of a default swap is par minus the recovery value as determined by any future ISDA auction which takes place after a credit event. As of today, the value of this recovery is unknown, we do not even know if a credit event will occur. As our model is based on the expected value of the protection leg, the recovery rate used has to be the expected value of the recovery rate conditional on a default and for this, market practitioners refer to historical recovery rates. Market convention is to use a 40% recovery rate as this is close to the average historical recovery

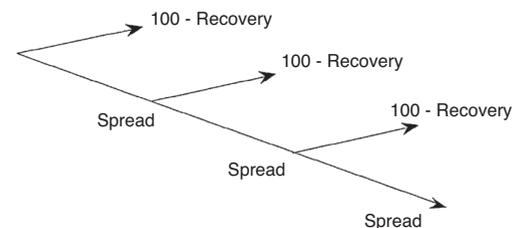

Figure 2 Payoff and Payment Structure of a CDS where as a simple approximation we assume that a credit event can only occur on a CDS premium leg payment date. In practice the credit event can occur at any time and the market standard model would take this into account.

rate for senior unsecured US corporate bonds – most CDS are linked to bonds which are senior unsecured.

In practice the portion of the premium payment that has accrued from the previous coupon payment date is paid by the protection buyer following the credit event. We have ignored it in our analysis since its effect on the calculated spread is small.⁷

Valuation of a Credit Default Swap

The valuation of CDS can be broken down into two separate tasks. The first is the determination of the default swap spread, which should be paid by a protection buyer at the initiation of a trade. This has already been discussed. The second is to determine the value of an existing CDS position, which we call the *mark-to-market* (MTM) or the upfront value. They are the same.

Since the recouping of CDS contracts in 2009, we can no longer state that the MTM or upfront of a new trade is always zero. The effect of fixing the premium leg coupon means that the risk of the reference entity must now be embedded in the initial cost of protection.

Once a CDS position has been established, changes in the current market CDS spread will mean that the MTM begins to deviate from its initial value and must be determined by observing the current level of default swap spreads in the market. To see how this is done, consider the following example.

An investor sells protection on a high yield reference entity for five years at an agreed contractual spread of 500 basis points. By selling protection the investor is assuming the credit risk of the reference entity as though he was buying one of the reference entity's issued bonds. A year later the reference entity's credit rating has improved and the market quoted 4-year par CDS spread is at 100 basis points. What is the MTM or upfront value of the position?

To begin with, the MTM value of the contract to the investor is given by the difference between what the investor is expecting to receive

minus what they are expected to pay. As a result we can write

$$\text{MTM} = + \text{Present value of four years of risky premium payments of 500 basis points} - \text{Present value of protection for the remaining four years}$$

We can also write that the current four-year par CDS spread of 100 basis points is the current break-even spread. By definition, the current value of a new four-year "par" CDS contract with a coupon equal to the par CDS spread is zero so we can write

$$\text{Present value of four years of risky premium payments of 100 basis points} = \text{Present value of protection for the remaining four years}$$

Substituting, we write

$$\text{MTM} = + \text{Present value of four years of risky premium payments of 500 basis points} - \text{Present value of four years of risky premium payments at 100 basis points}$$

which can be rewritten as

$$\text{MTM} = + \text{Present value of four years of risky premium payments of 400 basis points}$$

To go any further we have to compute the expected present value of these 400-basis points payments. However these payments are only made until the maturity of the CDS or to the time of a credit event, whichever occurs first. To compute the MTM we therefore need to weight each premium payment by the probability that there is no credit event up until that payment date. We therefore write

$$\text{MTM} = 400 \text{ basis points} \times \text{RPV01}$$

where the RPV01 is the "risky" price value of a basis point (PV01). This is defined as the present value of a 1 basis points payment made until the contractual maturity date of the position or to

the date of a credit event, whichever is sooner. Mathematically, we can write the RPV01 as

$$\text{RPV01} = \sum_{j=1}^n \Delta_j p(j\tau) Q(j\tau)$$

where Δ_j is the year fraction for the payment j in the appropriate basis (typically Actual 360). For quarterly paying CDS, Δ_j is usually close to or equal to 0.25. Bringing this all together, we can write the MTM value of a long protection position as

$$\text{MTM} = +[S(t, T) - S(0, T)] \times \text{RPV01}[S(t, T), R]$$

and that of a short protection position as

$$\text{MTM} = -[S(t, T) - S(0, T)] \times \text{RPV01}[S(t, T), R]$$

where $S(0, T)$ is the contractual spread of the contract, T is the contractual maturity date and $S(t, T)$ is the current par CDS spread to the contractual maturity date. It is essential to note that the RPV01 is a function of the market spread $S(t, T)$ and the assumed recovery rate R since both are used to imply out the risk-neutral survival probabilities.

To crystallize all of this theory, we present in Table 3 the valuation of the trade introduced at the beginning of this section in which an investor sells \$10 million of five-year protection at 500 basis points and then wishes to mark it to market one year later when the market has a flat term structure at 100 basis points. For simplicity we have assumed a flat LIBOR term structure at 2.5%. We assume a recovery rate of 40%. In particular we show the quarterly coupon payment dates (we have ignored holidays and weekends for simplicity) and the corresponding values of P and Q , calibrated to reprice the term structure of default swap spreads.

We see that the current par CDS spread is 100 basis points, and that the risky PV01 of the position is 3.7247—the present value of four years of risky 1 basis points payments is 3.7247 basis points. The resulting MTM value is \$1,489,892. This makes sense. The market has valued the risk of four year protection on the reference entity at 100bp in spread terms, but the fixed

coupon is 500bp. A new investor wanting to sell four year protection is therefore being over-compensated and to correct for this, has to pay a large upfront cost.

CDS Risk and Sensitivities

Market practitioners using CDS usually consider two risk measures. First is the Credit01 or Spread01. This is the change in the MTM value of a CDS position for a 1 basis points parallel shift in the CDS curve. Then there is the Interest Rate 01 which is the change in the MTM value of a CDS position for a 1 basis points change in LIBOR. In practice the LIBOR sensitivity of a CDS is small, usually at least an order of magnitude less than that of the Credit01. This reflects the fact that a CDS is almost a pure credit play.

It is actually possible to make some simple approximations that make clear the dependence of the MTM on these inputs. First, we can approximate the CDS spread in terms of the risk-neutral annualized default probability p , and assumed recovery rate R , using the equation $S = p(1 - R)$. The interpretation is that the annualized spread received for assuming a credit risk should equal the annualized default probability times the loss on default, which in a CDS equals $(100\% - R)$. This approximation works very well in practice. If we assume a flat term structure of CDS spreads, approximate Δ with $1/4$, then we can approximate the MTM of a long protection position as

$$\text{MTM} = \frac{[S(t, T) - S(0, T)]}{4} \sum_{j=1}^N P(j\tau) \left[1 - \frac{S(t, T)}{1 - R} \right]^{j/4}$$

We can immediately draw a number of conclusions from this mathematical expression for the MTM value. First, the MTM value is not a linear function of the market spread $S(t, T)$. In fact the MTM value of a short protection position is convex in the market spread, just as the price of a corporate bond is convex in the yield. Furthermore, it is also clear that the recovery rate sensitivity of the MTM value is large when the market spread is large. This means that where the market spread is below, say, 300 basis points, one does not have to be so precise about the recovery rate assumption. However, if spreads become large (say, 300 basis points and above) the recovery rate sensitivity becomes increasingly significant and care must be taken in making a recovery rate assumption.

Calibrating the Recovery Rate Assumption

To be precise, the recovery rate assumption, R , is the assumed price of the cheapest-to-deliver asset into the CDS contract within 72 calendar days of the notification of the credit event. This is not known today. Nor can it be extracted from any market prices. In theory, this would be pos-

sible given the existence of an active and liquid digital default swap market. A digital default swap is a contract that pays the face value in the event of default—it is like a standard default swap but instead assumes a fixed recovery rate of zero. The ratio of the normal CDS spread and the digital default swap spread would equal $(1 - R)$. However, the lack of liquidity of the digital market makes this calibration approach impractical.

The usual starting point for calibrating recovery rates is to observe rating agency statistics. Both Moody's and S&P maintain significant databases of U.S. corporate bond defaults. Care must be taken to adjust any average recovery rates for country and sector effects. Recovery rates also have a link to the economic cycle. In recent years, average recovery rates have fallen well below the long-term averages computed by rating agencies. One reason why this is so is that Moody's, for example, defines the recovery rate of a bond as the price of that bond within some short period following the default. It is not the final value received by holders of the bond after going through the workout process. This means that the recovery rate is driven by the size of the bid for the bond in the distressed debt market. In periods of credit weakness, the distressed debt market is unable to absorb the oversupply of defaulted assets and the bid consequently falls.

Another consideration when marking recovery rate assumptions is to take into account that following a restructuring event, which is not a full default, the deliverable obligations may trade at higher prices than in a full default. Since rating agencies do not consider restructuring as a full default, this effect is not accounted for in their statistics. Typical recovery rates being quoted in the market for good quality credits vary between 30% and 45%.

When spreads are trading at very high levels of 1,000 basis points and above, it is important to look to the bond market to see if bond prices are revealing any information about the expected recovery rate in the event

of a default. For example, a recovery rate assumption of 40% would make no sense if one of the deliverable bonds into the CDS is trading at 30 cents on the dollar. In this case, the recovery rate assumption should clearly be moved below 30%.

The Practicalities of Unwinding a Credit Default Swap

A CDS is an over-the-counter (OTC) derivative contract. This means that unlike some other derivatives contracts it is not exchange traded. Instead it involves an agreement between two counterparties. As almost all CDS are traded within the framework of the ISDA Master Agreement, there is widespread standardization of the documentation of CDS and many counterparties are happy to trade these bilateral contracts in what is effectively a secondary market. To unwind a CDS before its maturity date, an investor may consider one of three courses of action:

1. Negotiate a cash upfront price with the original counterparty. The price should be the same as the MTM value calculated according to the model. In practice a bid-offer spread will have to be crossed. Part of this negotiation may involve some exchange of information as to the recovery rate assumptions used by both counterparties.
2. If the investor is shown a better upfront price by a counterparty different to the one with whom the initial trade was executed, they can ask to have the contract reassigned to this other counterparty and then close it out for a cash unwind value.
3. They may choose to enter into an offsetting position. For example, an investor who has sold protection for five years may decide a year later to close out the contract by selling protection for four years. The value of this combined position should exactly equal the model market to market.

Which one of these choices is made is usually determined by which is showing the best price.

Prior 2009 we would have said that option 3 is different from the others because it leaves the CDS holder with an ongoing position consisting of a future stream of risky cashflows equal to the difference between the spread of the initial contract and that of the new unwind contract. However now that CDS contracts on the same reference entity all trade with the same coupon, option 3 actually now leaves the parties with no net cashflows as both coupon streams will cancel each other. Instead the CDS unwind value is realised through the upfront cost of the offsetting position and will be the same as options 1 and 2.

The matching of coupons means there is no economic value in retaining both positions and both positions can be cancelled. Indeed this effect was the purpose of fixing CDS coupons since it means that in future, major dealers in CDS will no longer be left with many tens of thousands of legacy partially offsetting positions and their associated counterparty risk. This reduces the gross notional of the CDS market and should reduce fears, unfounded or not, about systemic risk. It may also help to facilitate any future plans to migrate CDS contracts from the OTC market to an exchange traded market.

KEY POINTS

- There is a fundamental no-arbitrage relationship that links the pricing of credit default swaps and the bonds which they reference. Various market and contractual differences mean that this relationship is not strictly obeyed at all times. However material deviations from this relationship should not persist.
- Since the recouping of CDS contracts in 2009, CDS contracts no longer trade with zero initial value. The valuation of a CDS contract has become the process of determining the upfront value of a contract.
- A pricing model for CDS contracts needs to take into account the different factors that drive the pricing of CDS. These include the market implied term structure for the

probability of survival/default, the expected recovery price if there is a credit event, and the level of interest rates used to discount future cashflows.

- The role of the standard valuation model set out in this chapter is to determine this upfront value. As market prices are actually quoted in the form of a term structure of CDS par spreads, the model must be able to exactly refit these par spreads and to then use the implied survival curve plus assumptions about the expected recovery price to determine the upfront value of any given CDS contract.
- An implementation of the standard pricing model has been produced by the ISDA and is available from www.cdsmodel.com.

Valuation of Fixed Income Total Return Swaps

REN-RAW CHEN, PhD

Professor of Finance, Graduate School of Business, Fordham University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: A total return swap is a swap in which one party makes periodic floating rate payments to a counterparty in exchange for the total return realized on a reference asset (or underlying asset). The reference asset could be a credit-risky bond, a loan, a reference portfolio consisting of bonds or loans, an index representing a sector of the bond market, or an equity index. A total return swap can be used by asset managers for leveraging purposes and/or a transactionally efficient means for implementing a portfolio strategy. Bank managers use a total return swap as an efficient vehicle for transferring credit risk and as a means for reducing credit risk exposures. The Duffie-Singleton model can be used to value total return swaps.

In this entry we explain the valuation of total return swaps.¹ We begin with an intuitive approach.

AN INTUITIVE APPROACH

A typical *total return swap* is to swap the return on a reference asset for a risk-free return, usually the London Interbank Offered Rate (LIBOR). The cash flows for the swap buyer (that is, the total return receiver) are shown in Figure 1. In the figure, L_t is LIBOR at time t , s is the spread to LIBOR, and R_t is the total return at time t . The cash outlay at time t per \$1 of notional amount that must be made by the swap

buyer is $L_t + s$; the cash inflow at time t per \$1 of notional amount is R_t .

As a result, the pricing of a total return swap is to decide the right spread, s , to pay on the funding (that is, LIBOR) leg. Formally,

$$\hat{E}_0 \left\{ \sum_{j=1}^n \exp \left(- \int_0^{T_j} r(t) dt \right) [R_j - (L_j + s)] \right\} = 0$$

where r is the risk-free discount rate.

In words, the spread should be set so that the expected payoff of the total return swap is equal to zero. (We employ the standard risk-neutral pricing and discounting at the risk-free rate.) To make the matter simple (we shall discuss more rigorous cases later), we view r , R , and

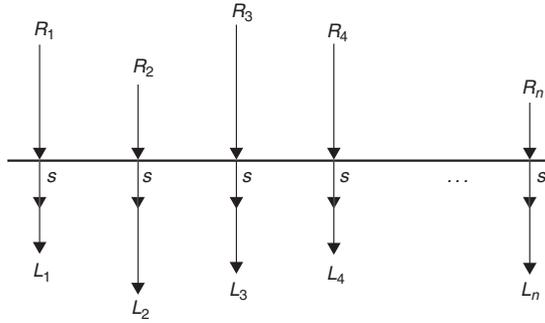

Figure 1 Cash Flows for the Total Return Receiver

L as three separate random variables. We then rearrange the above equation as

$$\begin{aligned} & \hat{E}_0 \left\{ \sum_{j=1}^n \exp \left(- \int_0^{T_j} r(t) dt \right) (R_j - L_j) \right\} \\ &= \hat{E}_0 \left\{ \sum_{j=1}^n \exp \left(- \int_0^{T_j} r(t) dt \right) \right\} s \end{aligned}$$

Exchanging expectation and summation of the right-hand side gives

$$\begin{aligned} & \hat{E}_0 \left\{ \sum_{j=1}^n \exp \left(- \int_0^{T_j} r(t) dt \right) \right\} \\ &= \sum_{j=1}^n \hat{E}_0 \left[\exp \left(- \int_0^{T_j} r(t) dt \right) \right] \\ &= \sum_{j=1}^n P(0, T_j) \end{aligned}$$

as the sum of risk-free pure discount bond prices. This implies

$$\begin{aligned} & \sum_{j=1}^n \hat{E}_0 \left[\exp \left(- \int_0^{T_j} r(t) dt \right) R_j - L_j \right] \\ &= \sum_{j=1}^n P(0, T_j) s \end{aligned}$$

The next step is to use the forward measure to simplify the left-hand side of the above equation:

$$\sum_{j=1}^n P(0, T_j) E_0^{F(j)} [R_j - L_j] = \sum_{j=1}^n P(0, T_j) s$$

Later, we show that the forward measure expectation of an asset gives the forward price of the asset. Hence, the left-hand side of the above equation gives two forward curves, one on the asset return, R , and the other on LIBOR, L :

$$\sum_{j=1}^n P(0, T_j) [f_j^R - f_j^L] = \sum_{j=1}^n P(0, T_j) s$$

where f_j^i is the forward rate of i ($i = R$ or L) for j periods ahead. Therefore, the spread can be solved easily as

$$s = \frac{\sum_{j=1}^n P(0, T_j) [f_j^R - f_j^L]}{\sum_{j=1}^n P(0, T_j)}$$

The result is intuitive: the spread is a weighted average of the expected difference between two floating-rate indexes. The weight is

$$\frac{P(0, T_j)}{\sum_{j=1}^n P(0, T_j)}$$

Note that all the weights should sum to one.

USING THE DUFFIE-SINGLETON MODEL

The difference in two floating rates is mainly due to their credit risk, otherwise they should both offer identical rates and give identical forward curves. As a consequence, to be rigorous about getting the correct result, we need to incorporate the credit risk in one of the indexes.

Among various choices, the model by Duffie and Singleton (1999) suits the best for this

situation. The *Duffie-Singleton model* is a popular reduced-form model that is used in credit risk modeling. In the model, the present value of any risky cash flow is defined as

$$C(t) = \left[\frac{S_{t+1} - S_t}{S_t} - L_{t+1} \right] N$$

where N is the notional, L is LIBOR, and S is the index level. As noted earlier, since both cash flows are random, it is a floating-floating swap. Also since the index is always higher than LIBOR because of credit risk, this swap requires a premium. As a result, the premium is computed as the sum of all future values, discounted and expected:

$$V = \sum_{j=1}^n \hat{E}_t \left[\exp \left(- \int_t^{T_j} [r(u) + q(u)] du \right) C(T_j) \right]$$

where q is the “spread” in the Duffie-Singleton model that incorporates the recovery rate and default probability.

THE FORWARD MEASURE

In this section, we show how the *forward measure* works and why a forward-adjusted expectation gives the forward value. We first state the separation principle that leads to the forward measure. Based on the no-arbitrage principle, the current value of any asset is the risk-neutral expected value of the discounted future payoff:

$$C(t) = \hat{E}_t \left[\exp \left(- \int_t^T r(u) du \right) C(T) \right]$$

The separation principle states that if we adopt the forward measure, then the above equation can be written as

$$C(t) = \hat{E}_t \left[\exp \left(- \int_t^T r(u) du \right) \right] E_t^{F(T)} [C(T)]$$

where $E_t^{F(T)} [\cdot]$ is the forward measure.² Note that the first term is nothing but the zero-coupon bond price:

$$P(t, T) = \hat{E}_t \left[\exp \left(- \int_t^T r(u) du \right) \right]$$

and hence

$$C(t) = P(t, T) E_t^{F(T)} [C(T)]$$

While we do not prove this result, we should note the intuition behind it. Let C be a zero-coupon bond expiring at time u . Then the above result can be applied directly and gives

$$P(t, s) = P(t, T) E_t^{F(T)} [P(T, u)]$$

or equivalently

$$E_t^{F(T)} [P(T, s)] = \frac{P(t, s)}{P(t, T)}$$

This is an indirect proof that the forward-adjusted expectation gives a forward value. The instantaneous forward rate can be shown to be the forward-adjusted expectation of the future instantaneous spot rate:

$$\begin{aligned} f(t, T) &= - \frac{d \ln P(t, T)}{dT} \\ &= - \frac{1}{P(t, T)} \hat{E}_t \left[\frac{d}{dT} \exp \left(- \int_t^T r(u) du \right) \right] \\ &= \frac{1}{P(t, T)} \hat{E}_t \left[\exp \left(- \int_t^T r(u) du \right) r(T) \right] \\ &= E_t^{F(T)} [r(T)] \end{aligned}$$

The discrete forward rates, $f_D(t, w, T)$ for all w and T , can also be shown to be the

forward-adjusted expectations of future discrete spot rates:

$$\begin{aligned} f_D(t, w, T) &= \frac{1}{\Psi(t, w, T)} - 1 \\ &= \frac{P(t, w)}{P(t, T)} - 1 \\ &= \frac{1}{P(t, T)} \hat{E}_t \left[\exp \left(- \int_t^T r(u) du \right) \frac{1}{P(w, T)} \right] - 1 \\ &= E_t^{F(T)} \left[\frac{1}{P(w, T)} - 1 \right] \end{aligned}$$

where $t < w < T$.

KEY POINTS

- A total return swap is a swap in which one party makes periodic floating rate payments to a counterparty in exchange for the total return realized on a reference asset such as a credit-risky bond.
- The pricing of a total return swap is to decide the right spread to pay on the funding leg.
- Using the standard risk-neutral pricing and discounting at the risk-free rate, the spread should be set so that the expected payoff of the total return swap is equal to zero.

- A reduced form model used in valuing credit derivatives, the Duffie-Singleton model, is employed to value total return swaps.
- The forward measure expectation of an asset gives the forward price of the asset that is the underlying for a total return swap.

NOTES

1. For a discussion of total return swaps and their applications, see Anson et al. (2004).
2. The derivation of this result can be found in a number of places. See, for example, Jamshidian (1987) and Chen (1996).

Pricing of Variance, Volatility, Covariance, and Correlation Swaps

ANATOLIY SWISHCHUK, PhD, DSc

Professor of Mathematics and Statistics, University of Calgary

Abstract: Swaps are useful for volatility hedging and speculation. Volatility swaps are forward contracts on future realized stock volatility, and variance swaps are similar contracts on variance, the square of future volatility. Covariance and correlation swaps are covariance and correlation forward contracts, respectively, of the underlying two assets. Using change of time method, one can model and price variance, volatility, covariance, and correlation swaps.

Variance, volatility, covariance, and correlation swaps are relatively recent financial products that market participants can use for volatility hedging and speculation. The market for these types of swaps has been growing, with many investment banks and other financial institutions now actively quoting volatility swaps on various assets: stock indexes, currencies, and commodities.

A stock's volatility is the simplest measure of its riskiness or uncertainty. In this entry we describe, model, and price variance, volatility, covariance, and correlation swaps.

DESCRIPTION OF SWAPS

We begin with a description of the different kinds of swaps that we will be discussing in this entry: variance swaps, volatility swaps, covariance swaps, and correlation swaps. Table 1 provides a summary of studies dealing with these swaps.

Variance and Volatility Swaps

A stock's volatility is the simplest measure of its riskiness or uncertainty. Formally, the volatility σ_R is the annualized standard deviation of the stock's returns during the period of interest, where the subscript R denotes the observed or "realized" volatility.

Why trade volatility or variance swaps? As mentioned in Demeterfi et al. (1999, p. 9), "just as stock investors think they know something about the direction of the stock market so we may think we have insight into the level of future volatility. If we think current volatility is low, for the right price we might want to take a position that profits if volatility increases."

The easiest way to trade volatility is to use *volatility swaps*, sometimes called realized volatility forward contracts, because they provide only exposure to volatility and not other risk. *Variance swaps* are similar contracts on variance, the square of the future volatility. As noted by Carr and Madan (1998), both types of swaps

provide an easy way for investors to gain exposure to the future level of volatility.

A stock volatility swap's payoff at expiration is equal to

$$N(\sigma_R(S) - K_{vol})$$

where $\sigma_R(S)$ is the realized stock volatility (quoted in annual terms) over the life of contract,

$$\sigma_R(S) = \sqrt{\frac{1}{T} \int_0^T \sigma_s^2 ds}$$

σ_t is a stochastic stock volatility, K_{vol} is the annualized volatility delivery price, and N is the notional amount of the swap in dollar per annualized volatility point.

Although options market participants talk of volatility, it is variance, or volatility squared, that has more fundamental significance.¹ A variance swap is a forward contract on annualized variance, the square of the realized volatility. Its payoff at expiration is equal to

$$N(\sigma_R^2(S) - K_{var})$$

where $\sigma_R^2(S)$ is the realized stock variance (quoted in annual terms) over the life of the contract; that is,

$$\sigma_R^2(S) = \frac{1}{T} \int_0^T \sigma_s^2 ds$$

K_{var} is the delivery price for variance, and N is the notional amount of the swap in dollars per annualized volatility point squared. The holder of variance swap at expiration receives N dollars for every point by which the stock's realized variance $\sigma_R^2(S)$ has exceeded the variance delivery price K_{var} . Therefore, pricing the variance swap reduces to calculating the square of the realized volatility.

Valuing a variance forward contract or swap is no different from valuing any other derivative security. The value of a forward contract P on future realized variance with strike price K_{var} is the expected present value of the future payoff in the risk-neutral world:

$$P_{var} = E\{e^{-rT}(\sigma_R^2(S) - K_{var})\}$$

where r is the risk-free interest rate corresponding to the expiration date T , and E denotes the expectation. Thus, for calculating variance swaps we need to know only $E\{\sigma_R^2(S)\}$, namely the mean value of the underlying variance.

To calculate volatility swaps we need more. Using the Brockhaus and Long (2000) approximation (which is the second-order Taylor expansion for function \sqrt{x}) we have²

$$E\{\sqrt{\sigma_R^2(S)}\} \approx \sqrt{E\{V\}} - \frac{Var\{V\}}{8E\{V\}^{3/2}}$$

where $V = \sigma_R^2(S)$ and $\frac{Var\{V\}}{8E\{V\}^{3/2}}$ is the convexity adjustment.

Thus, to calculate the value of volatility swaps

$$P_{vol} = \{e^{-rT}(E\{\sigma_R(S)\} - K_{vol})\}$$

we need both $E\{V\}$ and $Var\{V\}$.

Later we explicitly solve the Cox-Ingersoll-Ross³ equation for the *Heston model* for *stochastic volatility*⁴ using the change of time method and present the formulas for price variance and volatility swaps for this model.

Covariance and Correlation Swaps

Options dependent on exchange rate movements, such as those paying in a currency different from the underlying currency, have an exposure to movements of the correlation be-

tween the asset and the exchange rate. This risk can be eliminated by using a covariance swap.

A *covariance swap* is a covariance forward contract of the underlying rates S^1 and S^2 , which have a payoff at expiration that is equal to

$$N(Cov_R(S^1, S^2) - K_{cov})$$

where K_{cov} is a strike price, N is the notional amount, and $Cov_R(S^1, S^2)$ is a covariance between two assets S^1 and S^2 .

Logically, a *correlation swap* is a correlation forward contract of two underlying rates S^1 and S^2 whose payoff at expiration is the following

$$N(Corr_R(S^1, S^2) - K_{corr})$$

where $Corr(S^1, S^2)$ is a realized correlation of two underlying assets S^1 and S^2 , K_{corr} is a strike price, and N is the notional amount.

Pricing covariance swaps, from a theoretical point of view, is similar to pricing variance swaps, since

$$Cov_R(S^1, S^2) = 1/4\{\sigma_R^2(S^1 S^2) - \sigma_R^2(S^1/S^2)\}$$

where S^1 and S^2 are two underlying assets, $\sigma_R^2(S)$ is a variance swap for the underlying assets, and $Cov_R(S^1, S^2)$ is a realized covariance of the two underlying assets S^1 and S^2 .

Thus, we need to know the variances for $S^1 S^2$ and for S^1/S^2 . Correlation $Corr_R(S^1, S^2)$ is defined as follows:

$$Corr_R(S^1, S^2) = \frac{Cov_R(S^1, S^2)}{\sqrt{\sigma_R^2(S^1)}\sqrt{\sigma_R^2(S^2)}}$$

where $Cov_R(S^1, S^2)$ is defined as above and $\sigma_R^2(S^1)$ is the realized variance for S^1 .

Given two assets S_t^1 and S_t^2 with $t \in [0, T]$, sampled on days $t_0 = 0 < t_1 < t_2 < \dots < t_n = T$ between today and maturity T , the log-return of each asset is

$$R_i^j = \log\left(\frac{S_{t_i}^j}{S_{t_{i-1}}^j}\right), \quad i = 1, 2, \dots, n, \quad j = 1, 2$$

Covariance and correlation can be approximated by

$$\text{Cov}_n(S^1, S^2) = \frac{n}{(n-1)T} \sum_{i=1}^n R_i^1 R_i^2$$

and

$$\text{Corr}_n(S^1, S^2) = \frac{\text{Cov}_n(S^1, S^2)}{\sqrt{\text{Var}_n(S^1)}\sqrt{\text{Var}_n(S^2)}}$$

respectively.

MODELING AND PRICING OF VARIANCE, VOLATILITY, COVARIANCE, AND CORRELATION SWAPS WITH STOCHASTIC VOLATILITY

In this section, we explicitly solve the Cox-Ingersoll-Ross equation for the stochastic volatility Heston model, using the change of time method, and present the formulas for price variance, volatility, covariance, and correlation swaps for this model.

Stochastic Volatility: Heston Model

Let $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$ be a probability space with filtration \mathcal{F}_t , $t \in [0, T]$. Assume that the underlying asset S_t in the risk-neutral world and variance follow the following model (see Heston, 1993):

$$\begin{cases} \frac{dS_t}{S_t} = r_t dt + \sigma_t dw_t^1 \\ d\sigma_t^2 = k(\theta^2 - \sigma_t^2)dt + \gamma\sigma_t dw_t^2 \end{cases} \quad (1)$$

where r_t is the deterministic interest rate, σ_0 and θ are short and long volatility, $k > 0$ is the reversion speed, $\gamma > 0$ is the volatility (of volatility) parameter, and w_t^1 and w_t^2 are independent standard Wiener processes.

The Heston asset process has a variance σ_t^2 that follows a Cox-Ingersoll-Ross process, described by the second equation in (1). If the volatility σ_t follows the Ornstein-Uhlenbeck process (see, for example, Øksendal, 1998), then

Itô's lemma shows that the variance σ_t^2 follows the process described exactly by the second equation in (1). Note that if $2k\theta^2 > \gamma^2$, then $\sigma_t^2 > 0$ with $P = 1$ (see Heston, 1993).

Solving the equation for variance σ_t^2 in (1) explicitly using the change of time method gives

$$d\sigma_t^2 = k(\theta^2 - \sigma_t^2)dt + \gamma\sigma_t dw_t^2 \quad (2)$$

and takes the following form:

$$\sigma_t^2 = e^{-kt}(\sigma_0^2 - \theta^2 + \tilde{w}^2(\phi_t^{-1})) + \theta^2 \quad (3)$$

where $\tilde{w}^2(t)$ is an \mathcal{F}_t -measurable one-dimensional Wiener process, and ϕ_t^{-1} is an inverse function to ϕ_t :

$$\phi_t = \gamma^{-2} \int_0^t \{e^{k\phi_s}(\sigma_0^2 - \theta^2 + \tilde{w}^2(s)) + \theta^2 e^{2k\phi_s}\}^{-1} ds \quad (4)$$

This result simply follows from the following substitution

$$v_t = e^{kt}(\sigma_t^2 - \theta^2) \quad (5)$$

into the equation (2) instead of σ_t^2 .

Note that if $2k\theta^2 > \gamma^2$, then $\sigma_t^2 > 0$ with $P = 1$ (see, for example, Heston, 1993). From (5) it follows that

$$v_t e^{-kt} + \theta^2$$

is strictly positive too. If we take the integrand in the last integral we obtain

$$\begin{aligned} & [e^{k\phi_s}(\sigma_0^2 - \theta^2 + \tilde{w}^2(t)) + \theta^2 e^{2k\phi_s}]^{-1} \\ &= [e^{2k\phi_s}(e^{-kt}(\sigma_0^2 - \theta^2 + \tilde{w}^2(t))) + \theta^2]^{-1} \\ &= [e^{k\phi_s} \sqrt{e^{-kt}(\sigma_0^2 - \theta^2 + \tilde{w}^2(t)) + \theta^2}]^{-2} \\ &= [e^{k\phi_s} \sqrt{e^{-kt}v_t + \theta^2}]^{-2} \end{aligned}$$

since $v_t = \sigma_0^2 - \theta^2 + \tilde{w}^2(t)$. In the above integrals, the expression under the square root sign is positive and the square root is well defined. Hence, the last expression and therefore, the integrand in the integral in (4), are strictly positive. It means that ϕ_t is a monotone function and there exists an inverse function ϕ_t^{-1} in (3).

Valuing of Variance and Volatility Swaps

From previous results we get the following expression for the price of a variance and volatility swap.

The value (or price) P_{var} of a variance swap is

$$P_{var} = e^{-rT} \left[\frac{1 - e^{-kT}}{kT} (\sigma_0^2 - \theta^2) + \theta^2 - K_{var} \right] \tag{6}$$

and the value (or price) P_{vol} of volatility swap is approximately

$$P_{vol} \approx e^{-rT} \left\{ \left(\frac{1 - e^{-kT}}{kT} (\sigma_0^2 - \theta^2) + \theta^2 \right)^{1/2} - \left(\frac{\gamma^2 e^{-2kT}}{2k^3 T^2} [(2e^{2kT} - 4e^{kT} kT - 2)(\sigma_0^2 - \theta^2) + (2e^{2kT} kT - 3e^{2kT} + 4e^{kT} - 1)\theta^2] \right) / \left[8 \left(\frac{1 - e^{-kT}}{kT} (\sigma_0^2 - \theta^2) + \theta^2 \right)^{3/2} \right] - K_{vol} \right\} \tag{7}$$

The same expressions for $E[V]$ and for $Var[V]$ also may be found in Brockhaus and Long (2000).

Valuing of Covariance and Correlation Swaps

To value a covariance swap the following must be calculated

$$P = e^{-rT} (ECov(S^1, S^2) - K_{cov}) \tag{8}$$

To calculate $ECov(S^1, S^2)$ we need to calculate $E\{\sigma_R^2(S^1 S^2) - \sigma_R^2(S^1/S^2)\}$ for the two underlying assets S^1 and S^2 .

Let $S_t^i, i = 1, 2$, be two strictly positive Ito's processes given by the following model

$$\begin{cases} \frac{dS_t^i}{S_t^i} = \mu_t^i dt + \sigma_t^i dw_t^i \\ d(\sigma_t^i)^2 = k^i (\theta_t^i - (\sigma_t^i)^2) dt + \gamma^i \sigma_t^i dw_t^j, \quad i = 1, 2, j = 3, 4 \end{cases}$$

where $\mu_t^i, i = 1, 2$, are deterministic functions, $k^i, \theta^i, \gamma^i, i = 1, 2$, are defined in a similar way as in (1), standard Wiener processes $w_t^j, j = 3, 4$, are independent, $[w_t^1, w_t^2] = \rho_t dt, \rho_t$ is deterministic function of time, $[,]$ means the quadratic covariance, and standard Wiener processes $w_t^i, i = 1, 2$, and $w_t^j, j = 3, 4$, are independent.

We note that

$$d \ln S_t^i = m_t^i dt + \sigma_t^i dw_t^i$$

where

$$m_t^i := \left(\mu_t^i - \frac{(\sigma_t^i)^2}{2} \right)$$

and

$$\begin{aligned} Cov_R(S_T^1, S_T^2) &= \frac{1}{T} [\ln S_T^1, \ln S_T^2] \\ &= \frac{1}{T} \left[\int_0^T \sigma_t^1 dw_t^1, \int_0^T \sigma_t^2 dw_t^2 \right] \\ &= \frac{1}{T} \int_0^T \rho_t \sigma_t^1 \sigma_t^2 dt \end{aligned}$$

Let us show that

$$[\ln S_T^1, \ln S_T^2] = \frac{1}{4} ([\ln(S_T^1 S_T^2)] - [\ln(S_T^1/S_T^2)]) \tag{9}$$

First, note that

$$d \ln(S_t^1 S_t^2) = (m_t^1 + m_t^2) dt + \sigma_t^+ dw_t^+$$

and

$$d \ln(S_t^1/S_t^2) = (m_t^1 - m_t^2) dt + \sigma_t^- dw_t^-$$

where

$$(\sigma_t^\pm)^2 := (\sigma_t^1)^2 \pm 2\rho_t \sigma_t^1 \sigma_t^2 + (\sigma_t^2)^2$$

and

$$dw_t^\pm := \frac{1}{\sigma_t^\pm} (\sigma_t^1 dw_t^1 \pm \sigma_t^2 dw_t^2)$$

Processes w_t^\pm above are standard Wiener processes by the Levi-Kunita-Watanabe theorem and σ_t^\pm are defined above.

In this way, we obtain that

$$\begin{aligned} [\ln(S_t^1 S_t^2)] &= \int_0^t (\sigma_s^+)^2 ds = \int_0^t ((\sigma_s^1)^2 + 2\rho_t \sigma_s^1 \sigma_s^2 \\ &\quad + (\sigma_s^2)^2) ds \end{aligned} \tag{10}$$

and

$$\begin{aligned} [\ln(S_t^1/S_t^2)] &= \int_0^t (\sigma_s^-)^2 ds = \int_0^t ((\sigma_s^1)^2 - 2\rho_t \sigma_s^1 \sigma_s^2 \\ &+ (\sigma_s^2)^2) ds \end{aligned} \quad (11)$$

From (9)–(11) we have directly formula (8):

$$[\ln S_T^1, \ln S_T^2] = \frac{1}{4}([\ln(S_T^1 S_T^2)] - [\ln(S_T^1/S_T^2)]) \quad (12)$$

Thus, from (12) we obtain that

$$Cov_R(S^1, S^2) = 1/4(\sigma_R^2(S^1 S^2) - \sigma_R^2(S^1/S^2))$$

Returning to the valuation of the covariance swap in (8) we have

$$P = E\{e^{-rT}(Cov(S^1, S^2) - K_{cov})\} = \frac{1}{4}e^{-rT}(E\sigma_R^2(S^1 S^2) - E\sigma_R^2(S^1/S^2) - 4K_{cov})$$

The problem now has reduced to the same problem as above, but instead of σ_t^2 we need to take $(\sigma_t^+)^2$ for $S^1 S^2$ and $(\sigma_t^-)^2$ for S^1/S^2 (with $(\sigma_t^\pm)^2 = (\sigma_t^1)^2 \pm 2\rho_t \sigma_t^1 \sigma_t^2 + (\sigma_t^2)^2$), and proceed with similar calculations as for the variance and volatility swaps.

NUMERICAL EXAMPLE: VOLATILITY SWAP FOR S&P60 CANADA INDEX

In this section, we apply the analytical solutions provided above to price a swap on the volatility of the S&P60 Canada Index for five years (January 1997–February 2002).⁵

Suppose that at the end of February 2002 we wanted to price the fixed leg of a volatility swap based on the volatility of the S&P60 Canada Index. The statistics on log returns for the S&P60 Canada Index for the five years covering January 1997–February 2002 are presented in Table 2.

From the statistical data for the S&P60 Canada Index log returns for the 5-year historical period (1,300 observations from January 1997 to February 2002) it may be seen that the data

Table 2 Statistics on Log Returns S&P60 Canada Index

Series:	LOG RETURNS S&P60 CANADA INDEX
Sample:	1 1300
Observations:	1300
Mean	0.000235
Median	0.000593
Maximum	0.051983
Minimum	-0.101108
Std. Dev.	0.013567
Skewness	-0.665741
Kurtosis	7.787327

exhibit leptokurtosis. If we take a look at the S&P60 Canada Index log returns for the 5-year historical period, we observe volatility clustering in the return series. These facts indicate the presence of conditional heteroscedasticity. A GARCH(1,1) regression is applied to the series and the results are obtained as in Table 3. This table allows one to generate different input variables for the volatility swap model.

We use the following relationships: $\theta = \frac{V}{dt}$, $k = \frac{1-\alpha-\beta}{dt}$, $\gamma = \alpha\sqrt{\frac{\xi-1}{dt}}$, to calculate the following discrete GARCH(1,1) parameters:

- ARCH(1,1) coefficient $\alpha = 0.060445$
- GARCH(1,1) coefficient $\beta = 0.927264$
- The Pearson kurtosis (fourth moment of the drift-adjusted stock return) $\xi = 7.787327$
- Long volatility $\theta = 0.05289724$; $k = 3.09733$
- $\gamma = 2.499827486$
- Short volatility $\sigma_0 = 0.01$

Parameter V may be found from the expression $V = \frac{C}{1-\alpha-\beta}$, where $C = 2.58 \times 10^{-6}$ is defined in Table 3. Thus, $V = 0.00020991$; $dt = 1/252 = 0.003968254$.

Applying the analytical solutions (6) and (7) for a swap maturity T of 0.91 years, we find the following values:

$$E\{V\} = \frac{1 - e^{-kT}}{kT}(\sigma_0^2 - \theta^2) + \theta^2 = 0.3364100835$$

Table 3 Estimation of the GARCH(1,1) Process

Dependent Variable: Log returns of S&P60 Canada Index Prices
 Method: ML-ARCH
 Included Observations: 1,300
 Convergence achieved after 28 observations

	Coefficient	Std. error	z-statistic	Prob.
C	0.000617	0.000338	1.824378	0.0681
Variance Equation				
C	2.58E-06	3.91E-07	6.597337	0
ARCH(1)	0.060445	0.007336	8.238968	0
GARCH(1)	0.927264	0.006554	141.4812	0
R-squared	-0.000791	Mean dependent var	-	0.000235
Adjusted R-squared	-0.003108	S.D. dependent var	-	0.013567
S.E. of regression	0.013588	Akaike info criterion	-	-5.928474
Sum squared resid	0.239283	Schwartz criterion	-	-5.912566
Log likelihood	3857.508	Durbin-Watson stat	-	1.886028

and

$$\begin{aligned}
 Var(V) &= \frac{\gamma^2 e^{-2kT}}{2k^3 T^2} [(2e^{2kT} - 4e^{kT} kT - 2)(\sigma_0^2 - \theta^2) \\
 &\quad + (2e^{2kT} kT - 3e^{2kT} + 4e^{kT} - 1)\theta^2] \\
 &= 0.0005516049969
 \end{aligned}$$

The convexity adjustment $\frac{Var(V)}{8E\{V\}^{3/2}}$ is equal to 0.0003533740855.

If the nonadjusted strike is equal to 18.7751%, then the adjusted strike is equal to

$$18.7751\% - 0.03533740855\% = 18.73976259\%$$

This is the fixed leg of the volatility swap for a maturity $T = 0.91$.

Repeating this approach for a series of maturities up to 10 years, we obtain the result shown in Figure 2 for the S&P60 Canada Index Volatility Swap. Figure 1 illustrates the nonadjusted

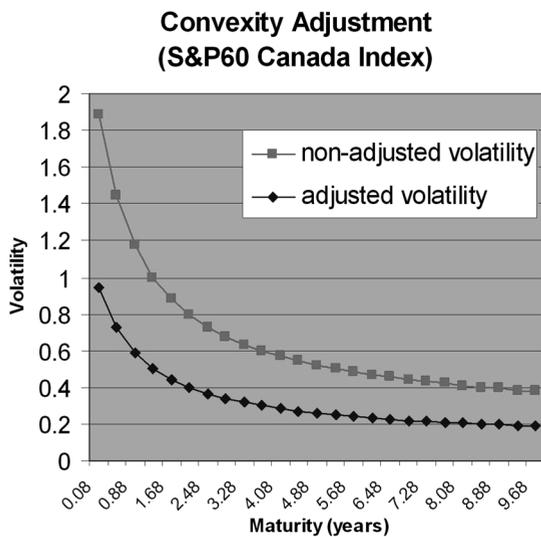

Figure 1 Convexity Adjustment

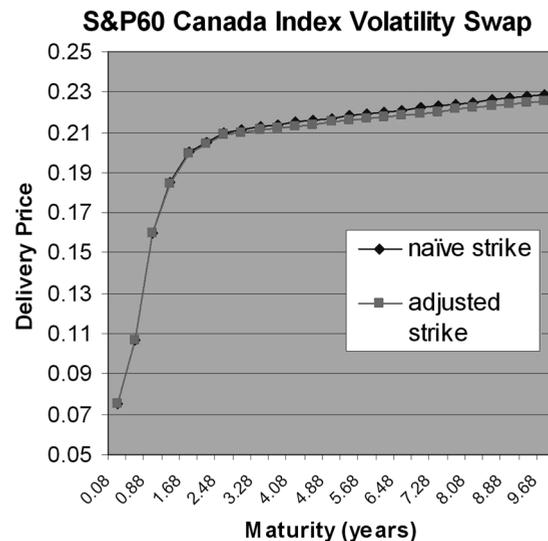

Figure 2 S&P60 Canada Index Volatility Swap

and adjusted volatility for the same series of maturities (see formula (7)).

KEY POINTS

- Variance, volatility, covariance, and correlation swaps are useful for volatility hedging and speculation.
- Volatility swaps are forward contracts on future realized stock volatility.
- Variance swaps are similar contracts on variance, the square of the future volatility.
- Covariance and correlation swaps are covariance and correlation forward contracts, respectively, of the underlying two assets.
- Using change of time one can model and price variance, volatility, covariance, and correlation swaps for the stochastic volatility Heston model.

Modeling, Pricing, and Risk Management of Assets and Derivatives in Energy and Shipping

PAUL D. SCLAVOUNOS, PhD

Professor of Mechanical Engineering, Massachusetts Institute of Technology

Abstract: Derivatives are financial contingent claims designed for the pricing, transfer, and management of risk embedded in underlying securities in the fixed income, equity, and foreign exchange markets. Their rapid growth spurred their introduction to the energy commodity and shipping markets where the underlying assets are real commodities, crude oil, refined products, natural gas, electricity, and shipping tonnage. Risk-neutral pricing and stochastic models developed for financial derivatives have been extended to energy derivatives for the modeling of correlated commodity and shipping forward curves and for the pricing of their contingent claims. This has enabled the valuation and risk management of a wide range of assets and derivatives in the energy and shipping markets. They include storage for natural gas, floating storage of crude oil, products and liquefied natural gas in tankers, refineries, power plants and utility scale wind farms, shipping structured securities, cargo vessels, and shipping derivatives portfolios.

Investments in energy and *shipping* assets are exposed to interest rate, commodity price, and freight rate risks. The management of these risks has led to the introduction and widespread use of *derivatives*, which have experienced explosive growth over the past several decades. In the fixed income market, interest rate *futures* and *futures options* emerged in the 1980s in response to the need to hedge interest rate swap risk. This led to the development of financial models for the arbitrage-free evolution of the term structure of interest rates and the pricing of a wide range of fixed income derivatives, laying the foundation for the development of analogous models for the

arbitrage-free evolution of the *forward curves* of physical commodities including crude oil, its refined products, natural gas, and recently shipping freight rates.

Commodity futures settle physically against the price of a spot commodity that must be delivered at the contract expiration or in cash against a spot commodity index. The latter is the case in shipping where *forward freight agreements* (FFAs) and freight rate futures settle against shipping indexes composed of a basket of freight rates. The first generation of commodity futures models was based on the development of stochastic models for the spot index and the use of the principles of

risk-neutral pricing for the valuation of derivatives written on the spot. Recent models are based on the insight that in the absence of arbitrage futures prices with daily credits and debits into a margin account are martingales. This has enabled the modeling of the evolution of futures prices of any tenor as lognormal diffusions with zero drift in a Gaussian setting. The primary unknown in this model of futures prices is the volatility term structure, which may be estimated from market prices of liquid futures and futures options. The arbitrage-free price process for the spot commodity or underlying index follows from this martingale representation of the entire commodity forward curve in the limit of small tenors.

The martingale representation of the commodity forward curve lends itself to a parsimonious modeling using the powerful statistical techniques of *principal components analysis* in the case of a single futures curve and of *canonical correlation analysis* in the case of multiple correlated forward curves. In both cases a small number of statistical factors may be derived, which are shown to follow mean reverting log-Ornstein-Uhlenbeck diffusions. This financial modeling and statistical inference framework of cross-correlated energy commodity and shipping forward curves allows the pricing of a wide range of vanilla, spread, and exotic derivatives written on futures contracts. Moreover, the model of the forward curve in terms of a small number of statistical factors enables the explicit valuation and *hedging* of a wide range of energy and shipping assets with cash flow exposures that may be replicated by the prices of traded futures contracts.

This entry reviews the fundamental developments that led to the introduction of financial and commodity derivatives, their stochastic modeling, and risk-neutral pricing. Pricing in Gaussian and non-Gaussian settings is addressed and shown in most cases to lead to closed-form results even when the underlying is represented by an advanced stochastic model. The martingale modeling of forward

curves and their estimation by a principal components analysis is discussed for the crude oil market, its refined products, natural gas, and the shipping market.

The valuation of real assets and financial claims of energy and shipping entities is discussed. The parsimonious form of the arbitrage-free factor models of the pertinent forward curves enable the pricing of these assets and securities by risk-neutral pricing. Their *risk management* is also addressed, drawing upon the explicit form of the underlying factor model and the techniques of *stochastic optimal control*, which have found widespread use for the management of portfolios of financial securities.

ENERGY COMMODITY PRICE MODELS

The past several decades have witnessed the emergence and rapid development of the fields of financial engineering and derivatives. Grown out of Paul Samuelson's foundational insights on the relationship between informationally efficient markets and the random walk and his introduction of the lognormal diffusion model of security prices, a wide range of stochastic models of security prices and arbitrage-free valuation methods were developed for the pricing of derivatives written on financial securities, real assets, and other variables (see Samuelson, 1965). The use of these models and pricing methods in the fixed income, equity, foreign exchange, and credit markets is growing as is the complexity of the mathematical, econometric, and filtering methods necessary for their implementation. More recently, these methods have been adapted to the energy and shipping sectors in order to control the high volatility of energy prices and freight rates and spur new investment.

Spot Price Models

Energy commodity prices are characterized by idiosyncrasies not encountered in the

financial markets. The volatility of the price of oil, natural gas, and especially electricity is a lot larger than that of currencies, interest rates, and equities. Energy prices often exhibit mean reversion, seasonality, and sharp and asymmetric spikes, which require the development of advanced price models and derivative valuation methods, extensions of the Black-Scholes-Merton stock option pricing formula. Moreover, a complex interaction often exists between the attributes of the spot physical commodity and its forward contracts and other derivatives that is not present for financial securities and their derivatives, which settle electronically and do not require the delivery of a physical asset. This requires the use of the extended *risk-neutral valuation* method of derivatives written on real assets and other variables that are not tradable (Ross, 1976).

Standard reduced form stochastic models for the spot price of crude oil and natural gas are diffusions that account for mean reversion and seasonality and depend on hidden economic factors. They include a stochastic convenience yield—the implied dividend received by the owner of the commodity held in storage—and a long-term stochastic equilibrium price to which the spot price mean reverts. The two-factor spot price models of Gibson and Schwartz (1990), Schwartz (1997), and Schwartz and Smith (2000) model the spot price and its factors as diffusions and permit the explicit valuation of futures and forward contracts and their options written on the spot commodity using the extended risk-neutral valuation of derivatives written on real assets (Hull, 2003). More general spot price models that may include stochastic volatility and jumps are discussed in Clewlow and Strickland (2000) and London (2007). In the study of Cortazar and Naranjo (2006) the entire oil futures curve and its volatility term structure are shown to be very well modeled by a four-factor spot price Gaussian model, which was estimated by Kalman filtering.

Stochastic models for the evolution of the electricity prices must account for sharp and asym-

metric spikes, strong mean reversion, jumps, and a dependence on structural factors affecting the electricity market. Reduced form stochastic models of electricity prices are usually jump-diffusions and Levy processes. An example is the jump-diffusion model of Kou (2002), which permits the independent parametric adjustment of the tail thicknesses of its probability distribution and allows the explicit pricing of electricity derivatives. Other models are discussed in Eydeland and Wolyniec (2003), London (2007), and Bength, Bength, and Koekebakker (2008). Analogous models apply to the modeling of the spot price process of shipping freight rates.

Forward Curve Models

Crude oil and natural gas have liquid futures contracts trading on the New York Mercantile Exchange (NYMEX) and the Intercontinental Exchange (ICE) with tenors of several years. For these commodities arbitrage-free forward curve models have been developed by Mil-tersen and Schwartz (1998), which accept as input the market prices of liquid futures and lead to the pricing of a number of other derivatives. The arbitrage-free evolution of the spot price follows from futures contracts of small tenors.

The modeling of the oil and natural gas futures curve is based on the Heath-Jarrow-Morton (HJM) framework developed for the arbitrage-free modeling of the term structure of interest rates. A principal task of the HJM framework is the parameterization of the volatility and correlation structure of the futures curve by a small number of independent factors using a principal components analysis. This was carried out by Scлавounos and Ellefsen (2009), where it was shown that three principal components capture most of the fluctuations of the forward curve. In the same paper the arbitrage-free evolution of the spot price was derived as implied in equilibrium by the forward curve and was shown to be driven by three independent factors that follow mean

reverting logarithmic Ornstein-Uhlenbeck (log-OU) processes with stochastic drifts. Calls, puts, swaps, caps, and their options written on futures contracts may then be valued explicitly as in the interest rate markets for use in energy risk management applications (Hull, 2003; Musiela and Rutkowski, 2005).

Energy Derivatives

In addition to the standard derivatives discussed above, more complex derivatives have been introduced in the energy markets reflecting the economics of energy assets. In particular, power plants are exposed to the spot/futures price difference of two *energy commodities*, for example, natural gas/electricity, coal/electricity; refineries are exposed to the price differentials of two fuels—crude oil/gasoline, crude oil/jet fuel; and oil and natural gas pipelines and electricity transmission lines are exposed to the price differentials of the same spot commodity at two different geographical locations.

A partial list of exotic derivatives used for the valuation, hedging, and risk management of energy assets include options on the spread between two futures contracts with different expirations written on the same commodity, options on the price difference of two futures contracts with the same expiration written on two separate commodities, options to exchange two spot commodities or their futures, average-price and average-strike Asian options, barrier options—which are exercised when the commodity price crosses a threshold—and American swing options for the delivery of an uncertain amount of the commodity. A discussion of these and other exotic energy derivatives is presented in Clewlow and Strickland (2000), Eydeland and Wolyniec (2003), and Geman (2005).

Exotic energy derivatives are complex to price and hedge for advanced commodity price models. Furthermore, spread derivatives depend not only on the volatility but also on the correlation between various spot/futures contracts,

which may be challenging to model and calibrate to market prices. Consequently, the development of accurate stochastic price models and pricing methods for exotic derivatives and spread options may be particularly helpful for the valuation and hedging of energy assets. Accurate analytical approximations of spread options prices and their hedge ratios are derived by Li, Deng, and Zhou (2008) for two assets that follow correlated log-OU diffusions. Extensions to multiasset spread option pricing and hedging are presented in Li, Zhou, and Deng (2010).

Shipping Derivatives

The success and rapid growth of derivatives in the energy commodity markets has spurred their introduction in the shipping markets. Shipping derivatives—forward freight agreements (FFAs) and freight futures—were introduced in 1985 and are widely used by the dry bulk and tanker shipping markets as discussed by Alizadeh and Nomikos (2009). Freight rate swaps were also recently introduced in the container ship markets. The growth of shipping derivatives is also motivated by the correlation of the supply and demand for shipping ton-miles with that of the bulk commodities transported by cargo vessels—crude oil, refined products, iron ore, and coal. An example is the recent introduction of over-the-counter iron ore swaps following the initiation of quarterly pricing of that bulk commodity. Therefore the need arises for the robust statistical modeling of the correlated forward curves of shipping and commodity markets and the pricing of shipping derivatives for use in risk management.

VALUATION AND HEDGING OF DERIVATIVES

The pricing of derivatives written on a financial security, a spot commodity, or another variable—the underlying—may be carried out by using the fundamental principles of risk-neutral valuation. When the underlying is a

nontradable—for example, temperature—an associated market price of risk process enters in the derivative price, which must be estimated from the prices of traded instruments. Otherwise, the fundamental economic insight of risk-neutral pricing and the associated mathematical techniques apply over a wide range of assets and stochastic models used for the modeling of the underlying process.

Vanilla Derivatives for Jump-Diffusions

A standard derivative pricing method for the wide class of jump-diffusion processes is based on the derivation of a risk-neutral probability measure under which European derivative prices may be expressed as conditional expectations of a payoff at a specified horizon (Duffie, 2001; Hull, 2003; Shreve, 2004; Musiela and Rutkowski, 2005). Derivative prices expressed as conditional expectations may be evaluated explicitly in the form of Fourier integrals of the complex characteristic function of the jump-diffusion by using the methods developed by Heston (1993), Carr and Madan (1998), Duffie, Pan, and Singleton (2000), and Lewis (2005). The use of this derivative pricing method in practice for the modeling of the equity-implied volatility surface and the calibration of a wide range of jump-diffusion models are discussed in Gatheral (2006).

Derivative prices expressed in the form of Fourier integrals allow the explicit evaluation of the derivative sensitivities known as the Greeks. They permit the analytical derivation of the stochastic process followed by the derivative price itself by using the Ito-Doebelin formula and often allow the explicit pricing of European derivatives with more general payoffs. The evaluation of Fourier integrals may be carried out efficiently by complex contour integration, numerical integration, or fast Fourier transform techniques.

The valuation of American options for jump-diffusions and the optimal stopping problems

that arise when early exercise is permitted is discussed in Oksendal and Sulem (2005). When the use of analytical techniques is not possible for the evaluation of American options and the determination of the early exercise boundary, the approximate method of Longstaff and Schwartz (2001), the quasi-analytical method described in Albanese and Campolieti (2006), and Monte Carlo simulation methods described in Glasserman (2004) may be used.

Exotic Derivatives for Jump-Diffusions

The valuation of a number of exotic derivatives is considerably more complex than their vanilla counterparts because their price depends on the path of the underlying process. Typical examples are barrier and Asian options. Therefore, the price of exotic derivatives is more sensitive on the structure of the underlying stochastic process than is the price of vanilla calls and puts. Consequently, the choice of the underlying process and the subsequent pricing and hedging of exotic derivatives may be a task of considerable complexity, a topic discussed for equities by Gatheral (2006).

For the geometric Brownian motion with constant drift and volatility, explicit prices of a number of exotic derivatives are derived in Shreve (2004). When the underlying process follows a jump-diffusion, the pricing of exotic derivatives by Fourier methods leads to Wiener-Hopf problems in the complex plane, the factorization of which is often possible analytically. This is the case for the jump-diffusion model of Kou (2002), which leads to the explicit valuation of barrier options. These analytical results are developed in Cont and Tankov (2004), where the class of Levy stochastic processes is also studied.

The extension of these Fourier methods to the valuation of options on spread contracts and other complex energy derivatives is discussed in London (2007). In the same reference the derivation of the characteristic functions of

a number of jump diffusion models of energy prices is presented along with the valuation of weather derivatives.

Statistical Inference of Asset Price Models

Asset price models usually contain a number of parameters that need to be estimated upon calibration of the model against market prices. This may be carried out by using the econometric techniques presented in Campbell, Lo, and MacKinlay (1997), Greene (2000), and Singleton (2006).

Stochastic models of commodity prices often contain hidden factors—stochastic trends, volatilities, and the convenience yield—which are usually modeled as diffusions. The estimation of the models may be carried out by casting the time series obtained upon discretization in state space form by using the methods presented by Durbin and Koopman (2001). The simultaneous inference of the model parameters and hidden factors may then be carried out by using dual Kalman filters and the expectations maximization algorithm presented in Haykin (2001). These statistical inference techniques may also be used for the estimation of nonlinear structural form models of power prices and shipping freight rates, which are known to depend on nonlinearities in the supply and demand schedules of the underlying markets.

Stochastic Optimal Control Methods

The availability of analytical models governing the evolution of spot commodity prices and their derivatives allows the formulation and solution of a wide range of valuation and hedging problems involving energy assets and their derivatives. The resulting stochastic dynamic programming problems are often possible to treat analytically by using the stochastic optimal control methods presented in Yong and Zhou (1999) for diffusions with

time-dependent deterministic coefficients. These results follow from the solution of the Hamilton-Jacobi-Belman (HJB) partial differential equation or the Pontryagin stochastic maximum principle and its connection to backwards stochastic differential equations. Extensions of these stochastic optimal control methods for underlying processes that follow diffusions with stochastic coefficients are discussed in Lewis (2005). Stochastic control methods for jump-diffusions and the treatment of the associated integro-differential equations are discussed in Oksendal and Sulem (2005).

APPLICATIONS

The stochastic price models, derivative valuation methods, and stochastic optimal control algorithms presented above have found widespread use in the securities markets. A number of applications drawn from the energy and shipping sectors are discussed below.

Valuation of Natural Gas and Oil Storage

Storage facilities for natural gas and oil are assets that enable the transfer of power generation capacity between two time periods in response to supply and demand fluctuations. Such fluctuations are affected by the different seasonal variations of the natural gas and electricity prices, the former usually being higher and more volatile during the winter and the latter often being a lot higher during the summer.

The availability of inexpensive gas storage facilities and the need to invest in new capacity allows the low-cost shifting of cheap summer production and storage of gas into the winter season. Moreover, the availability of gas storage facilities allows the quick delivery of natural gas when demand peaks, circumventing the need for expensive new production.

These economic drivers call for the valuation and optimal operation of storage facilities for natural gas and other fuels, in the face of stochastic gas prices, which are assumed to be unaffected by the availability of storage.

The storage valuation problem may be cast in a stochastic dynamic programming framework that relies on the analytical modeling of the commodity spot prices, futures curve, and their derivatives as outlined above. In its generality, this valuation problem reduces to the determination of optimal storage in/out-flows given the commodity seasonal price dynamics. The analytical framework for this valuation problem is presented in Eydeland and Wolyniec (2003) and discussed below in the context of the valuation of *crude oil floating storage* using a principal components factor model for the forward curve.

Valuation of Flexible Hydrocarbon Reservoirs

The optimal dynamic management of proven but undeveloped hydrocarbon reservoirs and flexible oil fields leads to a sequence of decisions analogous to those described above for above-ground storage facilities. When significant irreversible investments with option-like value are necessary for the development of flexible hydrocarbon fields, the extended valuation framework of real options is needed. Its development is presented in Dixit and Pindyck (1994), and a number of applications are discussed in Brennan and Trigeorgis (2000) and Copeland and Antikarov (2001). Given an HJM model for the oil and natural gas futures curve and its derivatives, the operation of flexible hydrocarbon fields may be reduced to a stochastic dynamic programming problem leading to the determination of optimal investment and hydrocarbon extraction flows. A number of real projects where these valuation methods are applicable are presented in Ronn (2002).

Hedging of Fuel Costs

The risk management of fuel costs in the transportation and energy sectors entails the hedging of commitments to purchase or deliver energy commodities—crude oil, natural gas, aviation jet fuel, gasoline, heating oil, and shipping bunker fuels by various entities—refineries, utilities, airlines, and shipping companies. An objective of such hedging programs is the minimization of the variance of the commodity price exposures over a given horizon. Variance-minimizing quadratic hedges of complex derivative exposures using simpler securities is common in the financial markets and may be reduced to the solution of a stochastic dynamic programming problem (Yong and Zhou, 1999; Jouini, Cvitanic, and Musiela, 2001).

A fuel cost hedging program may be implemented by using a combination of physical storage and the futures market. Such a hedging task faces a number of challenges, including commodity price and volume uncertainty, a decreasing liquidity of futures contracts of increasing tenor, an increasing volatility of futures contracts of decreasing tenor that need to be rolled over, and exposure to basis risk when liquid futures contracts for the fuel of interest do not exist. The solution of the resulting dynamic optimization problem may be carried out by taking advantage of the analytical modeling, pricing, and optimal control techniques outlined above. The complexity of such hedging programs is considerable as is highlighted by the collapse of the stacked hedges of Mettalgeshellschaft studied in Culp and Miller (1999).

Valuation of Seaborne Energy Cargoes

Crude oil and other liquid energy cargoes transported in tanker fleets may be traded while the cargo is in transit. This is akin to the optimal financial management of energy commodities in movable storage. Here, the location and speed

of the tankers enter as controls in a stochastic dynamic programming framework, which may be treated with the analytical techniques described above. The timing, sales price, and port of delivery of the energy cargo are variables that may be selected in a value-maximizing manner while the commodity is in transit. These decisions must take into consideration the shape of the oil futures curve, which may be trading in contango, backwardation, or in a composite formation, as well as the tanker freight rate forward curve. Moreover, since a large portion of the above-ground crude oil is in transit, the aggregate tonnage and average speed of crude oil tanker fleets may have a material impact upon the crude oil convenience yield, the shape of its futures term structure, and its impact on the valuation of seaborne oil.

The principal components model of the crude oil forward curve developed by Sclavounos and Ellefsen (2009) was applied by Ellefsen (2010) to the valuation of crude oil floating storage. The value of a crude oil cargo carried by a very large crude carrier (VLCC) is shown to be that of an American option with an embedded early exercise premium. The valuation of this option is carried out in a semianalytical form by virtue of the explicit form of the Ornstein-Uhlenbeck diffusions and their transition densities that govern the independent factors that drive the crude oil forward curve, using the method presented in Albanese and Campolieti (2006). It is shown that the value of the early exercise premium can be significant, particularly in volatile markets and even if the forward curve is not trading in extreme contango. The returns of crude oil floating storage investments are also studied and shown to be significant. Their hedging using crude oil futures is also addressed.

The valuation methodology developed for crude oil floating storage extends with minor modifications to land-based storage of crude oil, products, bunker fuels, natural gas, and other commodities. The necessary analytical machinery lies in the development of the principal component analysis of the forward curve

of the commodity under consideration and the analytical derivation of the diffusions governing a small number of independent factors that drive the evolution of the respective forward curves.

Analogous considerations apply to the transportation of liquefied natural gas in LNG carriers. The LNG market is not as liquid or global as the oil market, yet it is likely to mature in the future in light of the growing demand for natural gas for the generation of electricity.

Fuel-Efficient Navigation and Optimal Chartering of Shipping Fleets

The shipping industry consumes approximately 5% of the world oil production in the form of bunker fuels. Assuming a daily world oil production of 87 million barrels and a long-term price of oil of \$100 per barrel, the daily bunker fuel costs for the shipping industry are estimated at \$400 million. The long-term daily average freight rate revenue is harder to estimate and is assumed to be over twice the daily bunker fuel costs.

The selection of the optimal speed and route of cargo vessels exposed to stochastic freight rates and subject to the constraints imposed by the charter contract, cargo loading schedules, and port and other fees leads to a stochastic dynamic programming problem. The ship resistance and propulsion characteristics may be supplied by the shipowner, estimated from models or inferred from real-time measurements of the ship speed, propeller revolutions, engine performance, and the weather using the inference methods described in Haykin (2001). Using a reduced form or structural stochastic price model for the shipping freight rate forward curve, optimal routing and chartering strategies may be derived analytically aiming to minimize the fuel consumption and maximize freight rate revenue over single or consecutive voyages. A cumulative 5% reduction in bunker fuel costs and increase in freight rate revenue

would translate into a \$50 million increase in the daily net income of the shipping industry. The promise of these advanced dynamic optimization algorithms is underscored by their adoption by the aviation industry for the optimal routing of commercial jets (“Calculating Costs in the Clouds,” *The Wall Street Journal*, March 6, 2007).

Valuation and Hedging of Power Plants and Refineries

The optimal economic dispatch of power plants presents a challenging problem that depends in part on the price differential of two energy commodities. The input commodity is usually a fuel—natural gas or oil—which may be traded in the spot and forward markets. The output commodity is electricity, which cannot be stored. It trades into a spot cash market and may not have liquid forward contracts, as discussed by Joskow (2006).

In simple cases, the valuation of power generating units may be reduced to the pricing of a strip of options written on the price differentials of electricity and the input fuel, for example natural gas. Given analytical price models for the price of the input fuel and electricity, the power plant valuation and hedging problem may be based on the pricing of these spark-spread options, which may be available explicitly. In more general settings where operational constraints apply, the valuation problem may be cast in a stochastic dynamic programming framework, which may benefit from the use of the analytical modeling and hedging methods outlined above. A similar set of issues arise in the valuation and hedging of refineries that process crude oil, which has a well-developed spot and futures market, into products—gasoline, heating oil, jet fuel, bunker fuel—which often do not have actively traded forward contracts. The use of this general valuation and hedging methodology in practice is presented in Eydeland and Wolyniec (2003).

Valuation of Wind Farms and Electricity Storage Facilities

Wind is an ample, clean, renewable energy source, yet its availability is variable. Consequently the electricity generated from a wind farm varies stochastically and is a function of the statistical properties of the wind speed averaged over a certain time interval. The volatility of the annual mean wind speed is typically about 10%. The development of onshore wind farms is growing at a 25–35% rate worldwide. Offshore wind energy is the next frontier with high expected growth rates over the next several decades from the development of vast expanses of sea areas with high winds and capacity factors of 40–45% using innovative low-cost floating wind turbine technologies that may be deployed in water depths ranging from 30 to several hundred meters. An offshore wind farm with a rated capacity of 1 GW and a lifespan of 25 years is on an energy-equivalent basis comparable to a 100 million barrel oil reservoir. Moreover, this energy resource is available just 100 meters above sea level as opposed to thousands of meters below it.

The valuation of a utility scale onshore or offshore wind farm as an energy asset may be carried out using the standard weighted average cost of capital (WACC) discounted cash flow method for a constant capital structure. Alternatively the adjusted present value (APV) method may be used for a varying leverage ratio and when tax shields and other incentives available to wind farm investments must be valued separately. Wind turbines are high-value capital assets that generate steady cash flows with an annualized volatility of about 10%. Utility-scale wind farm investments may therefore be structured using nonrecourse project finance with a leverage that may reach 70–80%. The risk embedded in debt and equity securities used to finance utility-scale wind farm investments depends on technical, environmental, and market factors. Their rational modeling permits the pricing of debt and equity financial

claims at various levels of leverage. Moreover, the availability of robust long-term statistical models of the mean wind speed and shorter term jump-diffusion models of wind speed fluctuations and of the market prices of electricity discussed above allows the pricing of *structured securities* like convertible debt and other derivatives that may be used to design an optimal capital structure, hedge financial exposures of wind farms as energy assets, and determine the optimal mix between fixed PPA versus fluctuating market price contracts for the delivery of electricity.

Investments in large-scale storage facilities for electricity generated by wind farms may be economically attractive since they would permit the storage of kilowatt-hours when electricity prices are low and wind speeds are high and the sale of electricity when prices are attractive. Such large-scale storage facilities include pumped water storage in large reservoirs above ground or below sea level, compressed air storage in large underground caverns, high-capacity batteries, and compressed hydrogen in tanks following the electrolysis of seawater by onshore or offshore wind farms. The valuation and optimal operation of such storage depends on the short-term volatility and longer term fluctuations of wind speeds and electricity prices. Therefore its value is analogous to that derived from *natural gas storage*. The availability of a stochastic price model for the spot and forward electricity prices allows the explicit valuation of such storage facilities using the methods presented above. This analysis would suggest the merits, size, and optimal management of utility-scale electricity storage facilities and would guide investments in these assets.

Canonical Correlation of Commodity and Shipping Forward Curves

The principal components analysis of the term structure of interest rates and of the forward curves in the commodities markets is a pow-

erful method for the parsimonious modeling of the evolution of a large number of highly correlated spot and forward securities in the respective market. Examples of the application of this statistical modeling method were discussed above.

The forward curves of distinct energy commodities, for example, crude oil, gasoline, and gasoil, are often correlated. The same applies to the FFA forward curves of distinct routes in the dry bulk and tanker shipping markets. Therefore the development of parsimonious and robust statistical models of the correlation structure of two or more forward curves is often necessary for the valuation of assets exposed to multiple commodities. This may be accomplished by carrying out a canonical correlation analysis of the block covariance matrix of the commodity forward curves of interest. The diagonal blocks are the intracommodity covariance matrices, which may be treated by the principal component analysis discussed above. The off-diagonal blocks are the intercommodity covariance matrices, which may be reduced by the canonical correlation analysis described in Basilevsky (1994) and Anderson (2003).

In a principal components analysis a small number of dominant factors is derived for each commodity forward curve, linear combinations of the traded futures contracts of varying tenors. In a canonical correlation analysis, for example of two commodity forward curves, portfolios of futures trading on each forward curve may be derived that are maximally correlated. The maximum correlation coefficient between the two curves is a summary metric that is independent of the tenor of the futures contracts used to derive each portfolio. The extension of this method to multiple commodity forward curves is straightforward. A canonical correlation analysis allows an in-depth study of the cross-correlation structure of multiple commodity and shipping markets and may be used in the development of cross hedging strategies, in the valuation of assets, and for risk management.

The canonical correlation of the forward curves of distinct routes in the dry bulk and tanker shipping markets was carried out by Hatziyiannis (2010). This study revealed various degrees of maximal correlations between shipping routes and a surprisingly large maximal correlation between the dry bulk and tanker markets. This suggests that there exist portfolios of FFAs trading on major routes in the dry bulk market that are highly correlated with FFA portfolios in the tanker market. The composition of these portfolios follows from the canonical correlation analysis. The implication is that a few liquid forward curves in shipping may be used for the hedging of exposures in routes with less liquid derivatives. Moreover, maximally correlated portfolios of spot and forward contracts may be used for the design of broad shipping indexes across shipping sectors and routes that may spur the liquidity of shipping derivatives.

The shipping forward curve principal components and canonical correlation analysis described above may be extended to include cross-correlated energy and other bulk commodity forward curves. Combined with the powerful methods of conditional multivariate statistics coupled with robust Bayesian Stein estimators of drifts, risk management strategies of energy and shipping assets may be developed and trading strategies involving paper assets may be derived.

Pricing of Shipping Options

The arbitrage-free pricing of shipping options is carried out along lines similar to those in the energy markets. A technical complexity of shipping derivatives is that shipping options settle against the arithmetic average of the underlying spot index. Shipping options may be priced either by modeling the evolution of the underlying index, or by modeling the evolution of the underlying futures contract. The first method is prevalent to date and is discussed in Alizadeh and Nomikos (2009). Yet, the second method

has a number of advantages. By modeling the underlying futures or FFA contract as a lognormal diffusion, the pricing of calls and puts may be carried out readily by using the Black formula. Moreover, the underlying futures or FFA contracts may be used for delta, gamma, and vega hedging of options exposures.

This approach of pricing shipping options has been adopted in the multifactor principal components model of the forward curve developed by Sclavounos and Ellefsen (2009). It leads to explicit expressions of the option prices and their Greeks and also allows for a volatility term structure, which is the result of the mean reversion of the factors driving the shipping forward curves. The explicit form of the Ornstein-Uhlenbeck diffusions governing the evolution of the factors leads to explicit algebraic expressions for the options and their sensitivities discussed in Ellefsen (2010).

Pricing of Credit Risk and Structured Securities in Shipping

Shipping fleets are primarily financed by debt issued by banks and other lending institutions, followed by equity raised by shipping firms in private placements or on public exchanges. The underlying assets financed by this capital are cargo ships, which have observable prices quoted by shipping brokers. Credit derivatives and other structured securities analogous to those in widespread use in other asset markets are not yet as widely traded in the shipping sector.

The pricing of credit risk is based on the fundamental structural form firm value method of Merton (1974) and the reduced form hazard rate method of Duffie and Singleton (2003). These valuation methods have enabled the pricing of derivatives written on individual credits—for example, credit default swaps—as well as derivatives written on baskets of credits. The values of the underlying entities in a basket and their default probabilities are correlated, and this dependency structure may be

modeled in its generality by using multivariate Gaussian statistics and in non-Gaussian settings copulae functions. This financial technology has enabled the design and pricing of an array of structured financial securities discussed in Duffie and Singleton (2003), Lando (2004), London (2007), and Cherubini and Della Lunga (2007).

Shipping credit risk may be modeled and priced using a hybrid model, which blends the structural and reduced form valuation methods discussed in Ammann (2001). The price of the assets of a shipping firm—the cargo vessels—is stochastic but observable, therefore recovery at default is known. The price of equity of public shipping firms is also observable and may be used to model the hazard rate, the probability of default, and hence the pricing of shipping debt by calibrating a hybrid credit risk model as described by Overhaus et al. (2007). Cargo ship prices within and across shipping sectors are correlated, and this dependency may be modeled by identifying common underlying factors via a principal components and canonical correlation analysis. The above attributes of the shipping sector may be introduced to price loans, convertible bonds, equity and credit linked notes, and other structured securities, which may be used to better manage shipping risk, reduce bank regulatory risk capital, and make available new and innovative sources of financing to shipowners.

KEY POINTS

- Producers of energy commodities and owners of shipping tonnage may take short positions in futures and freight forward agreements (FFAs) in order to hedge their forward delivery commitments against a decrease of prices.
- Consumers of energy commodities and shippers who charter cargo vessels may take long positions in futures and FFAs in order to hedge their forward commodity and freight rate exposures against rising prices.
- Power plants and refineries that transform an input commodity into an output commodity, for example, natural gas to electricity, crude oil to gasoline, may go long the futures of the input commodity and short the futures of the output commodity in order to protect their profit margins against adverse moves of the input/output commodity price spread.
- Liquid energy commodity forward curves convey information about the stochastic evolution of the spot price of the commodity.
- The stochastic dynamics of individual energy commodity and shipping forward curves may be modeled by a small number of independent statistical factors using a principal components analysis (PCA). The factors are portfolios of traded futures contracts, and their stochastic dynamics are governed by diffusions that may be derived in explicit form.
- The joint stochastic dynamics of cross-correlated commodity and shipping forward curves may be modeled by a small number of statistical factors using an intracommodity PCA curve and an intercommodity canonical correlation analysis (CCA).
- The parsimonious statistical factor modeling of the commodity and shipping forward curves may be used for the valuation and risk management of energy assets, structured securities, and portfolios of commodity and shipping derivatives.

- for American options, *II:674*
 - with change of time, *III:522, III:524–525*
 - and diffusion equations, *II:654*
 - and Gaussian distribution, *II:732*
 - and Girsanov's theorem, *I:132–133*
 - statistical concepts for, *III:225*
 - use of, *I:126–127, I:136*
 - use of in MATLAB, *III:423–427, III:447*
 - use of with VBA, *III:462–463*
 - and valuation models, *I:271*
- Black-Scholes-Merton stock option pricing formula, *I:557*

- Black-Scholes model
 assumptions of, *I:512, III:655*
 and calibration, *II:681–682*
 for European options, *II:660–662, III:639–640*
 and hedging, *I:410*
 and Merton's model, *I:343*
 for pricing options, *I:487, I:509–510, I:522*
 usefulness of, *I:475*
 use of, *I:272*
 volatility in, *III:653*
- Black volatility, *III:548, III:550*
- Bohr, Niels, *I:123*
- Bond-price valuation model, *III:581–583*
- Bonds
 analytical models for, *I:271–273*
 annuities from, *I:211–212*
 calculating yields on, *II:618*
 callable, *I:24f, I:244–245, III:302–303, III:302f*
 capped floating rate, valuation of, *I:249f*
 changes in prices, *I:373–374*
 computing accrued interest and clean price of, *I:214–215*
 convertible, *I:230, I:271*
 corporate, *I:279, III:598–599*
 coupon-paying, *III:584–586*
 default-free, *I:223*
 determination of value of, *I:211–213*
 discount, *I:212*
 effective duration/convexity of, *I:255, I:256f*
 European convertible, *I:272*
 in European-style calls, *I:440*
 floating-coupon, *I:246–248, I:247f*
 floating-rate callable capped, *I:248*
 floating valuation, *I:253f*
 full (dirty) price, *I:214, I:370*
 futures contracts on, *I:498*
 general principles of valuation, *I:209–216*
 inflation-indexed, *I:278, I:279, I:283–290, I:290–294*
 input information for example, *III:613t*
 interest rate tree for, *I:244f*
 loading of specific, *II:279*
 modeling prices of, *I:490–494*
 and modified or effective duration, *III:299*
 nonpar, *I:232n*
 option-free, *I:241f, I:243*
 options on, *I:252–253, I:498–501, I:501–502*
 planned amortization class (PAC), *III:6*
 plot of convertible functions, *I:273f*
 prediction of yield spreads, *II:336–344*
 price/discount rate relationship, *I:215–216, I:215f*
 prices of, *I:213–214, I:278, I:382, II:727–728*
 prices with effective duration/convexity, *III:300t, III:301t*
 pricing for, *I:498–503, III:588*
 putable, effective duration of, *III:303–304, III:304f*
 regression data for spread application, *II:338–343t*
 relation to CDSs, *I:525–526*
 risk-free, *I:316*
 risk-neutral, *III:586*
 risk-neutral/equilibrium models for, *III:597–598*
 security levels of, *I:375t*
 spreads over time, *I:402f*
 straight, duration of, *III:301–302, III:301f*
 time path of, *I:216*
 valuation of, *I:213–215, I:216–223, I:223, II:730, III:576*
 valuing of, *I:213–214, I:244–246, I:246f*
 volatility of, *I:279*
- Book value, of companies, *II:535*
- Bootstrapping
 parametric, *II:428*
 of spot rate curve, *I:217–220*
 technique for, *II:711–712, II:746*
 usefulness of, *III:325*
 use of, *I:223, III:408*
- Borel functions, *III:508–509*
- Borel measures, *III:199, III:498*
- Borrowers, *III:5, III:70–71, III:74–75, III:598–600*
- Borrowing, *I:72–73, I:479–480*
- Boundary conditions, *II:660*
 need for, *II:661*
- Box-and-whiskers diagrams, use of, *III:329–330n*
- Boxplots, use of, *III:329–330n*
- Brennen-Schwartz model, *III:549*
- Brown, Robert, *III:476*
- Brownian motion, geometric (GBM), *I:95, III:656*
- Brownian motion (BM)
 arithmetic, *I:125, III:492, III:503*
 in binomial models, *I:114*
 bounds of, *III:473–474*
 canonical, *III:478*
 conditions defining, *III:483n*
 defined, *I:95, III:476–479*
 with drift, *III:491*
 early work on, *II:470*
 excursion of, *III:480*
 fractal properties of, *III:479–480, III:480f*
 generated by random walk, *III:479f*
 generating paths for in VBA, *III:463–465*
 geometric, *III:492–493, III:503, III:524*
 and Girsanov's theorem, *I:131, I:263*
 in Ito processes, *III:487–488*
 in Ito's formula, *III:488–489*
 and the Merton model, *I:306*
 one-dimensional standard, *III:477–478*
 paths of, *III:486, III:501–502, III:502f*
 path with deviation zones, *III:537f*
 process of, *I:269–270n*
 properties of, *III:479–481, III:501, III:536*
 in randomness calculations, *III:534–535*
 and stochastic integrals, *III:473*
 time-changed, *III:503–505*
 usefulness of, *III:495–496*
 use of, *I:262*
 variants of, *III:506*
- Bubbles, discovering, *II:396–399*
- Burmeister-Ibbotson-Roll-Ross (BIRR) model, *II:140*
- Burnout effect, *III:17–18, III:24, III:74*
- Burnout factor
 initializing of, *III:22*
- Business cycles, *I:351–352, I:408, II:430–431, II:432–433*
- Businesses, correlation within sectors, *I:411*
- Butterfly's wings, effect of, *II:645*
- Calculus, stochastic, *I:94–97*
- Calendarization, *II:43, II:487–488*
- Calibration
 of derivatives, *I:494*
 effect of, *III:619*
 under GIG model, *II:524*
 of local volatility, *II:681–685*
 need for, *III:604*
 to short forward curve, *III:545–546*
- Callable bonds, *I:462*
- Call options
 defined, *I:439*
 discrepancy measures across maturities of, *II:525t*
 early exercise of American-style, *I:442–443, I:449–450*
 European, *I:125, I:127–129, I:501, I:511, II:522–525, II:679*
 1998 prices of, *II:524t*
 value of, *I:259*

- Calls
 American-style, *I:441–442, I:449*
 error on value of, *II:668f*
 European-style, *I:440–441, I:448–449, I:448t*
- Canonical correlation analysis, *I:556*
- Capital asset pricing model (CAPM).
See CAPM (capital asset pricing model)

 cross-sectional, II:174–175, II:175t
 cumulative return of, II:234
 defined, II:691, II:697
 to describe default processes, I:313
 description and estimation of,
 II:256–257
 designing the next, III:590–591
 determining, II:299–300
 disclosure of, I:410
 documentation of, II:696
 dynamic factor, II:128, II:131,
 III:126–127
 dynamic term structure, III:591
 econometric, II:295, II:304
 equilibrium forms of, III:599–600
 equity risk, II:174, II:178–191, II:192
 error correction, II:381t, II:387–388,
 II:394–395
 evidence of performance, I:308–309,
 II:233
 examples of multifactor, II:139–140
 financial, I:139, II:479–480
 forecasting, II:112, II:303–304
 for forecasting, III:411
 formulation of, III:128–131
 fundamental factor, II:244, II:248
 generally, II:360–362
 Gordon-Shapiro, II:17–18
 Heath-Jarrow-Morton, III:586–587,
 III:589
 hidden-variable, II:128, II:131
 linear, II:264, II:310–311, II:348,
 II:507–508
 linear autoregressive, II:128,
 II:130–131
 linear regression, I:91, I:163–170,
 II:360, II:414–415
 liquidation process, I:342
 martingale, II:127–128, III:520–521
 MGARCH, II:371–372
 model-vetting procedure, II:696–697
 moving average, III:414
 multifactor, II:231–232, III:92
 multivariate extensions of,
 II:370–373
 no arbitrage, III:604

- nonlinear, *II:402–421, II:417–418*
